OBJECTIVE The predominant symptom of lumbar spinal stenosis (LSS) is neurogenic claudication or radicular pain. Some surgeons believe that the presence of substantial back pain is an indication for fusion, and that decompression alone may lead to worsening of back pain from destabilization associated with facet resection. The purpose of this study was to determine if patients with LSS and clinically significant back pain could obtain substantial improvements in back pain after a decompression alone without fusion.

METHODS The DaneSpine database was used to identify 2737 patients with LSS without segmental instability and a baseline back pain visual analog scale (VAS) score ≥ 50 who underwent a decompression procedure alone without fusion. Standard demographic and surgical variables and patient outcomes, including back and leg pain VAS score (0–100), Oswestry Disability Index (ODI), and EQ-5D at baseline and at 12 months postoperatively, were collected.

RESULTS A total of 1891 patients (69%) had 12-month follow-up data available for analysis; the mean age was 66.4 years, 860 (46%) were male, the mean BMI was 27.8 kg/m², and 508 (27%) were current smokers. At 12 months postoperatively, there were statistically significant improvements ($p < 0.001$) from baseline for back pain (72.1 to 42.1), leg pain (71.2 to 41.3), EQ-5D (0.35 to 0.61), and ODI (44.1 to 27.8).

CONCLUSIONS Patients with LSS, clinically substantial back pain, and no structural instability obtain improvement in back pain after decompression-only surgery and do not need a concomitant fusion.

KEYWORDS back pain; lumbar decompression; lumbar spinal stenosis; patient-reported outcomes; Oswestry Disability Index; EQ-5D

LUMBAR spinal stenosis (LSS) is caused by a combination of factors, including hypertrophy of joint capsules and ligaments, intervertebral disc protrusion, loss of intervertebral space height, and osteophytes. Surgery with decompression for LSS is the most common operation for degenerative spinal disease in the aging population.¹ There is substantial evidence for a superior clinical improvement by surgical decompression compared to prolonged conservative treatment.^{2–4}

The predominant symptom and main indication for decompression is neurogenic claudication or radicular pain, but low-back pain is also a common complaint. In the presence of predominant back pain, some authors recommend a concomitant fusion to alleviate the back pain.^{5,6} However, performing a supplemental fusion procedure

involves increased blood loss, operative duration, hospital stay, complication rate, and overall surgical cost.^{7,8} Recent studies have suggested an acceptable improvement of back pain with decompression only in patients with LSS.^{9–11} The aim of the present study was to clarify the clinical impact of decompression alone in patients with LSS and substantial back pain who were prospectively enrolled in the DaneSpine database.¹²

Methods

The DaneSpine database is a Danish national spine surgery database, prospectively collecting demographic and pre- and 12-month postoperative patient-reported outcomes (PROs). The database was queried to identify

ABBREVIATIONS LSS = lumbar spinal stenosis; MCID = minimal clinically important difference; ODI = Oswestry Disability Index; PRO = patient-reported outcome; VAS = visual analog scale.

TABLE 1. Patient demographics

Variable	Value
No. of patients	1891
Mean age (SD), yrs	66.4 (11.3)
Males (%)	860 (46)
Smokers (%)	508 (27)
Mean BMI (SD), kg/m ²	27.8 (5.0)

patients with the diagnosis of LSS without segmental instability and a baseline back pain visual analog scale (VAS) score ≥ 50 who underwent a decompression procedure without fusion. No segmental instability was defined as a spondylolisthesis less than 3 mm and no further slip on functional radiographs. The primary indication for surgery was leg pain and/or leg symptoms characteristic of LSS with a symptom duration longer than 3 months despite conservative treatment. The patients were operated on at three different Danish Spine units, and all had MRI findings concordant with the clinical symptoms. The type of decompression was performed according to the individual preference of the surgeon.

The threshold of a VAS back pain score ≥ 50 was selected, as this cutoff score might prompt some surgeons to add a fusion procedure. In concordance, a VAS back pain score ≥ 50 is used as an inclusion criterion in an FDA investigational device exemption study evaluating an interspinous process device versus instrumented fusion.¹³

Demographic data were collected, including age, sex, height, weight, smoking status, surgical variables, patient outcomes including back and leg pain VAS scores (0–100),¹⁴ and Oswestry Disability Index (ODI)¹⁵ and EQ-5D¹⁶ at baseline and 12 months postoperatively. Hence, the present study represents a longitudinal retrospective study of prospectively collected data. Statistical analyses were conducted using SPSS (version 25.0, IBM Corp.), and paired t-tests were applied to compare baseline PROs with 12-month PROs. The significance level was set at $p < 0.05$.

Results

A total of 2737 patients undergoing decompression for LSS and presenting VAS back pain scores ≥ 50 were identified, of whom 1891 patients (69%) had 12-month follow-up data available for analysis. The mean patient age was 66.4 ± 11.3 years, 860 (46%) were male, the mean BMI was 27.8 ± 5.0 kg/m², and 508 patients (27%) were current smokers (Table 1).

At 12 months' postoperative follow-up, there were statistically significant improvements from baseline in VAS back pain, VAS leg pain, ODI, and EQ-5D ($p < 0.001$, Table 2). The mean VAS back pain score was reduced from 72.1 to 42.1, and VAS leg pain score from 71.2 to 41.3. The ODI improved from 44.1 to 27.8 and the EQ-5D from 0.35 to 0.61. The ratio of patients reaching a minimal clinically important difference (MCID) was 59% ($n = 1123$) for ODI (MCID = 10),¹⁷ 67% ($n = 1269$) for VAS back pain (MCID = 18),¹⁷ and 57% ($n = 1076$) for VAS leg pain (MCID = 20).¹⁸

TABLE 2. Comparison of baseline and 12-month postoperative results

Scale	Baseline	1-Yr Follow-Up	p Value
VAS back pain, 0–100	72.1 (13.6)	42.1 (30.0)	<0.001
VAS leg pain, 0–100	71.2 (19.2)	41.3 (32.0)	<0.001
ODI, 0–100	44.1 (15.4)	27.8 (19.5)	<0.001
EQ-5D, 0–1.0	0.35 (0.31)	0.61 (0.31)	<0.001

Values are presented as the mean (SD) unless indicated otherwise.

Discussion

The rate of lumbar decompression for LSS has been steadily increasing in the elderly over the last decades.¹⁹ The relief of neurogenic claudication after surgery is well documented by the current literature.^{2–4} However, in the context of predominant back pain, it is debated whether an additional fusion is indicated.

In the present longitudinal retrospective study of prospectively collected data, we investigated the clinical effect of decompression without fusion in a subgroup of patients with LSS with claudication and a concurrent substantial back pain VAS score ≥ 50 . We demonstrated statistically and clinically significant improvements in self-reported back pain, leg pain, mobility, and quality of life in patients at the 1-year follow-up, based on VAS scores for leg and back pain, the ODI, and the EQ-5D.^{15,20–22} The reduction in back pain was similar to the reduction in leg pain, and the improvement in back pain surpassed the MCID in 67% of the 1891 patients at 12 months' follow-up. The results strongly suggest that despite substantial back pain, decompression without fusion is an appropriate treatment for patients with LSS and neurogenic claudication.

Our results are in concordance with the findings of recent studies based on a considerably smaller patient sample. Including all patients undergoing decompression for spinal stenosis, regardless of level of back pain at baseline, both Geiger et al. and Srinivas et al., respectively, found significant improvement in low-back pain in 33 patients with a follow up < 100 weeks,¹¹ and in 677 patients at 12 months' follow-up, of whom 68% reached the MCID.⁹ Our study solely included patients with preoperative VAS back pain scores ≥ 50 . Our findings therefore emphasize that an additional fusion should not routinely be added to the decompression in patients with LSS, even though back pain is substantial.

Crawford et al.¹⁰ likewise only analyzed patients with back pain scores ≥ 50 , and also demonstrated a significant reduction in both leg and back pain at 12 months' follow-up in 726 patients. They stratified patients according to the dominant symptom into the subgroups back pain–predominant group, leg pain–predominant group, and back pain equal to leg pain group. The MCID in the 3 groups was reached for back pain in 80%, 86%, and 84% of the patients, respectively.

The large sample size of the current cohort compared to previous studies constitutes a strength of the present study. Data were also collected prospectively. A potential weakness is that we did not stratify according to surgical technique of the decompression, which theoretically could

influence the outcome. However, previous studies indicated that this variable does not play a defining role.^{9,11,23} Our 12-month follow-up rate was 69%, slightly higher compared to the abovementioned studies. A previous dropout analysis of the DaneSpine database showed no influence on conclusions, and overall the nonresponders showed a better improvement in EQ-5D compared to the responders.¹² Thus, we do not believe the missing follow-up data confound the present findings. A longer follow-up than 12 months might show a different outcome, i.e., if the decompression entails a segmental instability over time, resulting in increasing back pain. However, a previous study with 10 years of follow-up showed sustained improvement in back pain.⁴

The impact of the length of substantial back pain might also influence the outcome. A short duration of back pain in the context of LSS may implicate back pain due to muscle spasms secondary to the leg symptoms. This type of back pain would theoretically be more amenable to improvement after the decompression relieves the leg symptoms. Conversely, a longer symptom duration of back pain might indicate degenerative changes as the underlying cause, which would not be alleviated by the decompression.

More patients in the present study reached an MCID for VAS back pain as compared to reaching an MCID for leg pain or ODI. We believe this is due to the inclusion criteria: only patients with a baseline VAS back pain score ≥ 50 were included, regardless of their baseline VAS leg pain or ODI score. The VAS leg pain and ODI scores consequently represented a broader range. Because the threshold of MCID for pain scores following surgery is lower, the higher the baseline score is, and more patients were likely to reach an MCID for VAS back pain.

Some authors advocate that substantial preoperative back pain is a predictor of poor outcome after surgery for LSS.²⁴ Our results, based on a large cohort of patients all presenting with substantial back pain, contradict this assumption. Our results are consistent with those of Srinivas et al., finding that an increased severity of back pain at baseline appeared to be associated with a higher likelihood of reaching the MCID for low-back pain improvement.⁹

Conclusions

In this study, patients with LSS, substantial back pain at baseline, and no structural instability obtained significant improvement in their back pain, comparable to their improvement in leg pain, after decompression-only surgery and may not need a concomitant fusion.
