OBJECTIVE The authors present the 10-year results of the Barrow Ruptured Aneurysm Trial (BRAT) for saccular aneurysms. The 1-, 3-, and 6-year results of the trial have been previously reported, as have the 6-year results with respect to saccular aneurysms. This final report comparing the safety and efficacy of clipping versus coiling is limited to an analysis of those patients presenting with subarachnoid hemorrhage (SAH) from a ruptured saccular aneurysm.

METHODS In the study, 362 patients had saccular aneurysms and were randomized equally to the clipping and the coiling cohorts (181 each). The primary outcome analysis was based on the assigned treatment group; poor outcome was defined as a modified Rankin Scale (mRS) score > 2 and was independently adjudicated. The extent of aneurysm obliteration was adjudicated by a nontreating neuroradiologist.

RESULTS There was no statistically significant difference in poor outcome (mRS score > 2) or deaths between these 2 treatment arms during the 10 years of follow-up. Of 178 clip-assigned patients with saccular aneurysms, 1 (< 1%) was crossed over to coiling, and 64 (36%) of the 178 coil-assigned patients were crossed over to clipping. After the initial hospitalization, 2 of 241 (0.8%) clipped saccular aneurysms and 23 of 115 (20%) coiled saccular aneurysms required retreatment ($p < 0.001$). At the 10-year follow-up, 93% (50/54) of the clipped aneurysms were completely obliterated, compared with only 22% (5/23) of the coiled aneurysms ($p < 0.001$). Two patients had documented rebleeding, both died, and both were in the assigned and treated coiled cohort (2/83); no patient in the clipped cohort (0/175) died ($p = 0.04$). In 1 of these 2 patients, the hemorrhage was not from the target aneurysm but from an incidental basilar artery aneurysm, which was coiled at the same time.

CONCLUSIONS There was no significant difference in clinical outcomes between the 2 assigned treatment groups as measured by mRS outcomes or deaths. Clinical outcomes in the patients with posterior circulation aneurysms were better in the coiling group at 1 year, but after 1 year this difference was no longer statistically significant. Rates of complete aneurysm obliteration and rates of retreatment favored patients who actually underwent clipping compared with those who underwent coiling.

THE 1-, 3-, and 6-year results of the Barrow Ruptured Aneurysm Trial (BRAT) have been previously reported.^{7,16,17} The 6-year results for saccular aneurysms have also been previously reported.¹⁸ In this work we are presenting the 10-year final follow-up of saccular aneurysms.

Because the BRAT used a prospective intent-to-treat design that randomized all patients with nontraumatic subarachnoid hemorrhage (SAH) to either coiling or clipping on the basis of initial CT findings, enrollment included patients with angiographically negative SAH, as well as

ABBREVIATIONS BRAT = Barrow Ruptured Aneurysm Trial; ISAT = International Subarachnoid Aneurysm Trial; mRS = modified Rankin Scale; SAH = subarachnoid hemorrhage.

those with fusiform, blister, dissecting, and saccular aneurysms, and those with aneurysms associated with an arteriovenous malformation or fistula.

Although the BRAT was specifically initiated to be compared with the International Subarachnoid Aneurysm Trial (ISAT), we did not predetermine in our protocol that we were limiting the analysis to saccular aneurysms. However, given that every other randomized trial comparing clipping and coiling has been limited to saccular aneurysms, an analysis of this cohort in BRAT is appropriate.

Methods

The study protocol for the BRAT was approved by the institutional review board of St. Joseph's Hospital and Medical Center, Phoenix, Arizona, on November 12, 2002, and is registered at ClinicalTrials.gov (NCT01593267). A detailed description of the study protocol was previously published.⁷ Briefly, all eligible patients with nontraumatic SAH who were admitted to the hospital between March 2003 and January 2007 were included. Of the 500 eligible patients, 29 were excluded (28 because consent was obtained in error and 1 because consent was rescinded), leaving 471 patients, of whom 238 were assigned to the intent-to-clip cohort and 233 to the intent-to-coil cohort.

Because there were no anatomical exclusion criteria, 6 categories of nontraumatic SAH were recorded: 1) non-aneurysmal SAHs, 2) aneurysms associated with arteriovenous malformations or fistulas, 3) fusiform aneurysms, 4) blister aneurysms, 5) dissecting aneurysms, and 6) saccular aneurysms.

Fifty-seven patients had a nonaneurysmal SAH. Although our 1-year outcome data included these untreated patients, they were excluded from further analysis in the 3-year and 6-year publications because these outcomes were not associated with any treatment decision, and the outcomes in this nontreated group were identical between the 2 assigned cohorts.¹⁶ Of the 414 remaining patients, 212 were randomized to clipping and 202 to coiling. After a patient was assigned to coiling or clipping, the treating

surgeon determined whether the assigned treatment was appropriate or whether the patient was best served by crossing over to the other treatment arm.

Aneurysm type was determined from angiographic studies, surgical inspection, and endovascular treatment. Because differences in aneurysm type are not always clear or well defined, as part of this post hoc analysis all nonsaccular aneurysms were rereviewed by a nontreating physician to assure the highest fidelity. Although some aneurysms were reclassified on review, statistical analysis revealed no significant difference between the initial and final adjudication. The final designation of aneurysm type for each lesion was used for this study. Saccular aneurysms represented 77% of all nontraumatic SAHs and 87% of all patients who received a diagnosis of an actual aneurysm. This report analyzes the outcomes of the 362 patients with saccular aneurysms.

Outcome Analysis

Follow-up data were collected at 6 months and at 1, 3, and 6 years and were collected for the current 10-year final follow-up report. The modified Rankin Scale (mRS) assessments were performed by a qualified research nurse independent of the treating physician. Adverse events were recorded as they occurred. Outcomes were analyzed on an intent-to-treat basis by the assigned treatment group. The 2 groups were well matched, with the exception of aneurysm location in the posterior circulation (Figs. 1 and 2).¹⁶ Additional data recorded included aneurysm type, outcome based on actual treatment, outcome of cross-over patients, rebleeding, death, aneurysm size, aneurysm location, and extent of aneurysm obliteration as assessed on imaging studies by a neuroradiologist not involved in treatment (R.C.W. or J.K.).

Results

Saccular aneurysms accounted for 76.8% (362/471) of all nontraumatic SAHs and 87.4% (362/414) of all patients

FIG. 2. Bar graph showing anatomical randomization of anterior circulation aneurysms. ACOM = anterior communicating artery; Ant = anterior; ICA = internal carotid artery; MCA = middle cerebral artery; Post com = posterior communicating artery; Prox = proximal.

who had aneurysms. For the 362 patients with saccular aneurysms enrolled in the BRAT, randomization resulted in equal assignments of 181 patients to each cohort and good parity of Hunt and Hess scores. In each cohort, 3 patients died before treatment, leaving 178 for treatment. Of the 178 clip-assigned patients with saccular aneurysms, 1 (< 1%) was crossed over to the coiling arm, and 64 (36%) of the 178 coil-assigned patients were crossed over to clipping arm.

Intent-to-Treat Analysis

For patients with saccular aneurysms, there was no sig-

nificant difference in mRS scores > 2 (Table 1) or deaths (Table 2) at any time during follow-up—from hospital discharge to 10 years posttreatment.

Sentinel Events

SAH and Deaths

There were 2 SAHs resulting in 2 deaths during the course of the study, at 7.5 and 9.5 years after treatment. Both patients were randomized to endovascular coiling and received that treatment (2/83). In 1 patient, the SAH was not from the target aneurysm but an incidental basilar artery aneurysm that was coiled at the time of the original

SAH. There was no SAH during the 10-year follow-up in the clipped cohort 0/175 ($p = 0.04$).

Retreatments

Aneurysm recurrence that required retreatment after discharge from hospital occurred in < 1% (2/241) of the patients whose aneurysms were clipped and in 20% (23/115; 3 patients underwent recoiling twice) of the patients who received coil treatment ($p < 0.001$).

Aneurysm Obliteration

Clipping resulted in sustained aneurysm obliteration over time, whereas aneurysm obliteration continued to decrease over time in the patients who underwent coiling (Table 3).

Analysis by Location

Posterior Circulation

For the saccular aneurysms located in the posterior circulation, endovascular treatment was favored at 1 year ($p = 0.03$) but did not reach significance at any other recorded time (Table 4). There was no statistically significant difference in deaths at any follow-up time.

Anterior Circulation

For the anterior circulation aneurysms, there was good parity of all anatomical sites between the 2 assigned treatments (Fig. 2). At 10 years and at all other times, there was

no significant difference in mRS scores > 2 between the clipping and coiling groups (Table 5).

For anterior circulation aneurysms, deaths over the 10 years of the study were at parity by assigned treatment at all times. On average, at 10 years 34% of the patients in both assigned cohorts had died; when the cases carried forward were included, 27% of patients in each cohort had died.

Discussion

The BRAT was an all-inclusive trial in which randomization occurred for all patients with nontraumatic SAH before the source of the hemorrhage was determined. The high cross-over rate of 36% in the coiled cohort in the BRAT would probably be less if the study were repeated today, but it underscores the extent of selection bias involved in the ISAT enrollment process. Thus, the only aneurysms randomized in the BRAT that would have qualified for the ISAT are those that were randomized to coiling and then were actually treated by coiling. In addition, in the ISAT there were few posterior circulation aneurysms (only 2.7%) and the average World Federation of Neurosurgical Societies grade and the Hunt and Hess grade was lower than in the BRAT. The all-inclusive design of the BRAT resulted in the inclusion of saccular, blister, fusiform, and dissecting aneurysms. Because all previous randomized trials^{5,6,8-11} have been restricted to saccular aneurysms, it is appropriate to analyze the BRAT for this same subgroup. This 10-year follow-up report provides the longest published follow-up of a cohort of non-selected patients with an SAH from a saccular aneurysm.

Among all the published prospective randomized trials of clipping versus coiling of saccular aneurysms that required equipoise for enrollment, only the ISAT claimed long-term benefit.^{5,6,9-11} The BRAT, like the ISAT, found a greater risk of subsequent SAH in the coiled cohort, probably from growth and recurrence of the aneurysm or coil compaction.³ In the ISAT, there was no requirement for postoperative documentation of aneurysms that were clipped, making it difficult to comment about the cause of the subsequent bleeds in that group. This lack of documentation has been a major criticism of the ISAT, and the high rebleeding rates in the clipped cohort are suspected

§ Includes patients seen at the 1-, 3-, or 6-year follow-up but not at the 10-year follow-up; it does not include patients no longer in the study or those who could not be contacted at the 1-, 3-, 6-, and 10-year follow-ups.

to be at least partially due to the quality of the surgical care.^{1,4,12,14,15} Indeed, in a report documenting the rate of retreatment in the ISAT,² it is noted that 30 (3%) patients randomized to clipping had no clip applied during their initial craniotomy, and of these, 26 were subsequently coiled. This situation, in a group of small, mostly anterior circulation aneurysms where equipoise was a prerequisite before randomization, supports the allegation of inadequate surgical expertise in the ISAT. In contrast, the BRAT had no equipoise requirement, and only 1 patient was crossed over from clipping to coiling (< 1%). The fact that there was no SAH in the 10 years of follow-up of all clipped aneurysms after discharge in the BRAT lends credence to these concerns.

In the BRAT, the intent was treatment within the first 24 hours of admission, with the result that there was absolutely no difference in the pretreatment morbidity and mortality between the 2 randomized cohorts. In the ISAT, there was a 15-hour longer delay for clipping versus coiling after randomization, leading to an additional 11 rebleeding episodes and 12 more deaths in the clipping group than in the coiling group before treatment. These data again raise a question regarding the full commitment of all the participating physicians to the study.⁸

In the BRAT, in which the extent of aneurysm obliteration

was documented at all specified follow-up times and adjudicated by nontreating neuroradiologists, there was a significant difference ($p < 0.001$) in the rate of complete aneurysm occlusion at 10 years that favored clipping over coiling; 93% (50/54) versus 22% (5/23) (Table 3). This difference explains the marked disparity noted in retreatment rates between the 2 study arms; 19% for the coiled cohort and < 1% for the clipped cohort ($p < 0.001$). The coiling retreatment rate was similar to that of the ISAT, in which 17.4% of coiled aneurysms were retreated.² The high obliteration rate for the clipped cohort in the BRAT is the rational explanation for there being no recorded SAH in this cohort at 10 years (0/175), versus the 2 SAHs that resulted in death in the coiled group (2/83) ($p = 0.04$) (Tables 3–5). The fact that these fatal hemorrhages occurred at 7.5 and 9.5 years after the initial SAHs emphasizes the risk of aneurysm regrowth over time and the lack of value in reporting aggregate patient-years because the risk of rebleeding increases with time.

For the long-term ISAT follow-up, the title (*The durability of endovascular coiling versus neurosurgical clipping of ruptured cerebral aneurysms: 18-year follow-up of the UK cohort of the International Subarachnoid Aneurysm Trial*) suggests 18 years of follow-up, but the results are actually provided for only 10 years. The ISAT showed

that there was no difference in dependency between the clipped and coiled cohorts but that there were statistically significantly more deaths in the clipped cohort.⁹ This was not the case in the BRAT, in which, at the 10-year follow-up, the death rates in the anterior circulation were essentially the same in both cohorts.

Study Limitations

This review of the BRAT results for saccular aneurysms has several limitations. It is a post hoc analysis of a single-center study, and the designation of aneurysm types is subjective. Nevertheless, it provides long-term follow-up of a real-world, unselected population of patients with ruptured saccular aneurysms whose treatment assignment did not require equipoise.

Conclusions

There are a variety of opinions and conclusions reached by various experts resulting in the continued quest for the optimal treatment of patients with aneurysmal SAH. We are in agreement with the ISAT authors that a new trial is warranted.¹³ A prospective intent-to-treat trial is the only way to provide a credible answer as to which management method provides the better long-term result. In the BRAT, in patients with anterior circulation aneurysms, the clipping cohort had better outcomes than the coiling cohort for rebleeding, retreatment, and aneurysm obliteration, although there was no difference in clinical outcomes between the 2 groups.
