Object. Thoracic pedicle screw fixation is effective and reliable in providing short-segment stabilization. Although the procedure is becoming more widely used, accurate insertion of the screws is difficult due to the small dimensions of thoracic pedicles, and the associated risk is high due to the proximity of the spinal cord. In previous studies authors have shown the accuracy of image-guided lumbar pedicle screw placement, but there have been no reported investigations into the accuracy of image-guided thoracic pedicle screw placement. The authors report their experience with such an investigation.

Methods. To evaluate the accuracy of image-guided thoracic pedicle screw placement in vitro and in vivo, thoracic pedicle screws were placed with an image-guidance system in five human cadavers and 10 patients. In cadavers, the accuracy of screw placement was assessed by postoperative computerized tomography and visual inspection and in patients by postoperative imaging studies. Of the 120 pedicle screws placed in five cadavers pedicle violation occurred in 23 cases (19.2%); there was one pedicle violation (4.2%) in each of the last two cadavers. Of the 45 pedicle screws placed in 10 patients, pedicle violations occurred in three (6.7%).

Conclusions. In comparison with historical controls, the accuracy of thoracic pedicle screw placement is improved with the use of an image-guidance system. It allows the surgeon to visualize the thoracic pedicle and the surrounding structures that are normally out of the surgical field of view. The surgeon, however, must be aware of the limitations of an image-guidance system and have a sound basic knowledge of spinal anatomy to avoid causing serious complications.

Keywords • neuronavigation • pedicle screw • thoracic spine • computer-aided surgery

The use of pedicle screw fixation has become a popular procedure in patients with trauma-induced fractures, as well as in reconstruction after treatment of degenerative, scoliotic, and neoplastic spinal diseases. For those with three-column injury, pedicle screw fixation provides the only means to accomplish immediate immobilization of all three columns without resorting to anterior and posterior procedures. Biomechanically, it is superior to instrumentation in which hooks are used, and it allows application of significant corrective forces. Moreover, pedicle screw fixation allows a fusion of fewer motion segments and does not require hardware that will intrude into the spinal canal.

Despite all of the advantages, thoracic pedicle screw placement is infrequently performed due to the difficulty of accurate screw placement. Thoracic pedicles are smaller and more variable in dimension compared with lumbar sacral pedicles. The risk from screw misplacement is higher because of the proximity of the spinal cord. Intraoperative fluoroscopic imaging of the thoracic pedicle is difficult because of radiographic obscuration from the rib cage. Therefore, it comes as no surprise that the rate of reported thoracic pedicle wall violation ranges from 15.9 to 54.7%. An image-guidance system is an obvious adjunctive tool for thoracic pedicle screw placement. The use of image guidance has been reported to increase the accuracy of lumbar pedicle screw placement. In five human cadavers and our early clinical experience in 10 patients in whom image-guided thoracic pedicle screw placement was conducted.

CLINICAL MATERIAL AND METHODS

Patient Population

Five cadavers (two male and three female individuals who were elderly at the time of death) and 10 patients underwent image-guided thoracic pedicle screw placement. The technical study was conducted first in cadavers at...
the University of California, Los Angeles, and then in 10 patients treated by the lead author (K.D.K.) from February 1999 to March 2000 at the University of California, Davis. There were seven men and three women, who ranged in age from 20 to 66 years (mean age 36.7 years). The pathological conditions included trauma (eight patients), degenerative disease (one patient), and tumor (one patient). All but one patient required an extension of the fusion to either the cervical or lumbar region (Table 1).

**Preoperative Preparation**

Computerized tomography scans of the spine were obtained in 1-mm slices, and the data were imported into one of the computer workstations: the Optical Tracking System (Radionics, Burlington, MA) for the cadavers and the Stealth Station (Medtronic, Broomfield, CO) for the patients. Both systems generated 3D images of the spine and standard 2D orthogonal images on the computer monitor.

**Surgical Technique**

After making a midline incision, posterior subperiosteal dissection was performed at the relevant levels to expose the spinous processes, laminae, and transverse processes. A reference frame was attached to the spinous process of each vertebra studied, and the registration was performed using the standard techniques.\(^1\),\(^6\),\(^9\). The registration step was repeated until the match was determined to be adequate.\(^9\) In the cadavers, our registration achieved a mean error of less than 1.5 mm whereas in patients the mean error was below 0.7 mm. The accuracy of the match between preoperative CT scans and postexposure anatomy was assessed by placing the probe onto an exposed anatomical landmark as the computer screen displayed the perceived location of that probe.

A power drill with a bit diameter of 2.5 or 3.5 mm was tracked by the image-guidance system.\(^10\) The computer monitor displayed the location of the drill bit and its trajectory on the axial, sagittal, coronal, and 3D images. Additional navigation views in relation to the plane of the instrument were also used. Each thoracic pedicle pilot hole entry point and trajectory was initiated, and the pedicle entered with a drill under image guidance. The pilot hole was then tapped and the screws (ranging in diameter from 3.5–6.5 mm) were placed, both without image guidance. Prior to insertion of the screw, a blunt-tipped image-guided probe was inserted into the proximal portion of the tap hole to assess the trajectory. The screw sizes varied due to the large differences in the pedicle width. The largest available screws that the pedicles could accommodate were used.

**Postoperative Evaluation**

A total of 120 thoracic pedicle screws was placed in the five cadavers. The accuracy was evaluated by postoperative CT scanning and visual inspection. The spine was removed from each cadaver and stripped of all the soft tissues. To assess lateral pedicle wall violation, the rib head attachments to the spine were removed using a rongeur. Using a saw to bisect the spine, the integrity of the medial, superior, and inferior pedicles was then evaluated. A total of 45 thoracic pedicle screws was placed in 10 patients. The accuracy of the pedicle screw placement was evaluated postoperatively by CT scanning and anteroposterior and lateral radiography. In all patients flexion–extension x-ray films were obtained 3 months after surgery except in Cases 5 and 8 because the patients were lost to follow up.

**RESULTS**

Of 120 thoracic pedicle screws inserted in cadavers, 23 (19.2%) resulted in pedicle wall violation (Table 2). There was a progressive decline in the perforation rate from 24% in the first cadaver to 4% in the last treated cadaver. A greater number of medial perforations (15 of 21) occurred than lateral perforations (eight of 21). Although seven

major perforations occurred medially, we did not find obvious injury to the dura. There was no superior or inferior pedicle wall perforation. No significant differences in the rate of pedicle wall violation were noted among the different thoracic levels.

Of 45 thoracic pedicle screws placed in the 10 patients, three (6.7%) resulted in pedicle wall violation, as demonstrated on postoperative images (Table 1). There were two lateral and one medial perforation, all minor (defined as only the threads of the screw extruding from the cortex).

One complication was recognized: the patient in Case 6 had a seroma and wound dehiscence that was repaired and healed without sequelae.

ILLUSTRATIVE CASES

Case 6

This 22-year-old schizophrenic man leapt from a bridge, suffering a C7–T1 fracture–dislocation and T-12 burst fracture; the results of the initial examination were consistent with a complete C-7 spinal cord injury. In addition, he sustained multiple extremity fractures and abdominal injuries.

He underwent a posterior C4–T3 fusion. The fixation construct consisted of lateral mass screws placed at C-4, C-5, and C-6 and pedicle screws placed at C-7, T-1, and T-2. The Stealth Station was used for image-guided placement of all pedicle screws (Fig. 1).

Postoperative CT scanning revealed good fracture reduction (Fig. 2 left) and accurate screw placement (Fig. 2 right), except for one minor lateral pedicle perforation at T-2. He was managed in a cervical collar for 3 months. At 3 months follow-up examination, flexion–extension x-ray films demonstrated no instability and good alignment of the spine.

Case 9

This 66-year-old man was struck by a falling tree as he walked down the street. He presented to the emergency room insensate and flaccid, with a complete T12 spinal cord injury and an L-1 burst fracture with T12–L1 fracture–dislocation. In addition, he suffered a perineal puncture wound, hemopneumothoraces, multiple extremity fractures, and a renal artery avulsion.

He underwent image-guided posterior thoracolumbar fusion in which pedicle screws were inserted bilaterally from T-11 to L-2 (Fig. 3 left). Postoperative CT scanning...

placement even more difficult.
mor involvement makes accurate thoracic pedicle screw
induced by degenerative changes, trauma, scoliosis, or tu-
of the thoracic pedicles impossible. Anatomical variation
often make good intraoperative fluoroscopic visualization
ference from the rib cage and the small size of the pedicles
racic pedicles varied significantly. Furthermore, the inter-
et al., concluded that the shape and orientation of tho-
er point and trajectory for thoracic pedicle screw place-
ment differ significantly among the experts. A
try point and trajectory are difficult to predict
because of the variable anatomy of the thoracic pedi-
er point of entry and trajectory to traverse the pedicle with-
the pedicle, allowing the surgeon to select the optimum
An image-guidance system provides multiplanar views of
screw placement. Anatomic variation induced by degenerative changes, trauma, scoliosis, or tu-
mor involvement makes accurate thoracic pedicle screw
placement even more difficult.

In a report on thoracic pedicle screw placement in ca-
davers, Vaccaro and colleagues did not use image guid-
ance. The five experienced spine surgeons reported a 41% pedicle perforation rate. Xu, et al. reported thoracic pedi-
perforation rate of 54.7%, when using the Roy-Ca-
mille technique; when they performed partial thoracic
laminecotomy to palpate the medial and superior walls of
the pedicle, the perforation rate decreased to 15.9%.

For thoracic pedicle screw placement in which even a
minor deviation in the screw trajectory may result in a
pedicle perforation, any improved visualization is inval-
able. A CT-based image-guidance system provides the
surgeon with a view of the pedicle and surrounding struc-
tures in multiple planes. For each pedicle, an ideal entry
point and trajectory for screw placement may be chosen.
An image-guidance system is able to track and provide
updated information about the location of the probe to
avoid injury to the spinal cord.

In ideal circumstances, the use of an image-guidance
system should eliminate all pedicle perforation. This,
however, has not been our experience. The key step is reg-
istration. Here the preoperative image is correlated in-
traoperatively with the patient’s anatomy. If the correlation
is suboptimal, the displayed image does not accurately re-

K. D. Kim, J. P. Johnson, and J. D. Babbitz

flect the position of the probe. This was reflected in the
increased perforation rate seen in cadavers compared with
patients, most likely due to the higher mean error achieved
during registration in the former. In thoracic pedicles, in
which the room for error is small, minor inaccuracies can
result in significant error and possible serious compli-
cations.

For the first three cadavers, our pedicle perforation rate
was higher than that reported by others for lumbar pedicle
screw placement. With any new technology there is an
associated learning curve, and we found this to be the case
with the image-guidance system. Some of the problems
were related to the hardware that was used. The early ref-
ence frame was so bulky that it got in the way of the sur-
gical instrument, and it could be inadvertently moved in-
dependent of the spinal segment, rendering the images on
the video monitor inaccurate.

Prior to and during an image-guidance system-assisted
procedure, the surgeon should be conscious of the sys-
tem’s limitations. If the surgeon blindly trusts what is dis-
played on the computer monitor, serious injury may be
caued to the patient and the construction may be bio-
mechanically unsound.

CONCLUSIONS

Thoracic pedicle screw placement allows strong fix-
ation of the spine without the need for long-segment fu-
sion. It is, however, technically challenging because of the
small size and variable dimensions of thoracic pedicles.
An image-guidance system provides multiplanar views of
the pedicle, allowing the surgeon to select the optimum
point of entry and trajectory to traverse the pedicle with-
out perforating the wall. If used properly, an image-guid-
ance system may prove to reduce significantly the pedicle
perforation rate and ultimately reduce the risks of thoracic
pedicle screw insertion.
