Object. The objective of this study was to assess the feasibility and efficacy of treating spondylolisthesis-related spinal stenosis via unilateral approach bilateral decompression in which METRx-MD instrumentation is placed.

Methods. Eight consecutive patients with spinal stenosis underwent bilateral decompressions via a unilateral approach in which METRx-MD instrumentation was placed. The procedures were performed on an outpatient basis after induction of general anesthesia. The patients underwent preoperative and 3-month postoperative plain radiography in which flexion–extension x-ray films were obtained. Preoperative and postoperative magnetic resonance imaging was also performed. All radiographs and neuroimages were read by a single radiologist blinded to the clinical results.

Eight vertebral levels in the eight patients were surgically decompressed (in one patient an additional level of non-spondylolisthesis-related stenosis was decompressed). The mean operative time was 92 minutes and the mean blood loss was 33 ml/level. Preoperatively stenosis was severe in five patients, moderate/severe in two, and moderate in one; postoperatively stenosis was absent in five, mild in two, and mild/moderate in one. Motion was detected on flexion–extension radiographs in three patients, but on early (3-month) postoperative radiographs there was no evidence of progression.

Conclusions. By following the authors’ procedure, minimally invasive bilateral decompression of acquired spinal stenosis associated with spondylolisthesis can be successfully performed on an outpatient basis, with reasonable operative times, minimal blood loss, and acceptable morbidity.

KEY WORDS • spinal stenosis • spondylolisthesis • laminotomy • minimally invasive surgery • outpatient surgery

In 1911 Bailey and Casamajor extensively described spinal stenosis as a cause of neural compression. Surgical treatment of spinal stenosis was undertaken as early as 1900.22 Traditional treatment of spinal stenosis has involved wide laminectomy and undercutting of the medial facet with foraminotomy.26 More limited decompressive procedures including bilateral foraminotomies24,27 and unilateral approaches to bilateral decompression14,20 have been shown to be effective.

Minimally invasive procedures involving chemical,23 mechanical,16,19 laser,3 and endoscopic techniques10,16,19 have been applied in spine surgery. Foley and Smith have popularized the microendoscopic discectomy technique for disc surgery. This technique has further evolved with the introduction of a microendoscopic tubular retractor system for microdiscectomy (METRx-MD) that improves compatibility with the operative microscope. The extension of the METRx-MD placement-related techniques to intraspinal pathological entities other than herniated discs has evolved, and surgeons are increasingly familiar and comfortable with such a technique. We implanted the METRx-MD instrumentation via a unilateral approach after performing bilateral decompression of acquired spinal stenosis in patients with Grade I degenerative spondylolisthesis.

CLINICAL MATERIAL AND METHODS

Patient Population
The first eight consecutive patients with spinal stenosis and Grade I spondylolisthesis to undergo bilateral decompression via a unilateral approach for and placement of METRx-MD instrumentation are included in this report. A single surgeon performed all surgeries. A total of eight spondylolisthetic levels were decompressed (in one patient an additional stenotic level, not involved with spondylolisthesis, was decompressed). Two discectomies were performed at the stenotic/spondylolisthetic levels. Motion was detected on flexion–extension radiographs in three patients, but on early (3-month) postoperative radiographs there was no evidence of progression.

The mean patient age was 70.5 years (range 49–83 years). There were seven women and one man. The duration of symptoms was 44 months with a mean of 19 months. There were no smokers. Back pain was present in...
seven, claudication in three, radiculopathy in eight, reflex abnormalities in five, motor abnormalities in three, sensory abnormalities in four, and bowel and bladder abnormalities in one.

Preoperative and Postoperative Assessments

All patients underwent pre- and postoperative MR imaging studies. A single radiologist (R.T.), blinded to the clinical results of decompression, reviewed all pre- and postoperative studies. The T₂-weighted axial MR images were graded with regard to the degree of stenosis: 0, none; 1, mild; 2, mild/moderate; 3, moderate; 4, moderate/severe; and 5, severe (Fig. 1). In all patients preoperative and in seven patients 3-month postoperative lumbar flexion–extension radiographs were obtained. These were reviewed for evidence of instability and/or progression of spondylolisthesis. Our office nurse (R.P.) interviewed all patients 4 to 7 months postoperatively to assess their clinical progress, using a basic questionnaire, which included a VAS for pain developed by PhDx for spinal surgery.

Surgical Procedure

Patients were prepared and positioned as for standard laminectomy. The procedure is a modification of the microendoscopic discectomy procedure previously described in detail by Foley and Smith. The level of interest was localized using fluoroscopy, and an 18-mm paramedian skin incision was then made. The muscle was sequentially dilated, and an 18-mm working channel, of the shortest length that would allow adequate depth of access (usually 50 or 60 mm), was placed. The operating microscope was moved into the field and the laminar edge was identified. A laminotomy was performed, extending cephalad to the insertion of the ligamentum flavum on the inferior surface of the superior lamina (to ensure adequate resection of ligamentous compressive elements) and caudally to include a smaller portion of the superior aspect of the inferior lamina, thus exposing the pedicle. Partial resection of the medial facet complex was performed as necessary to obtain an adequate decompression of the lateral recess and the foramina.

The working channel was then angled medially, exposing the anterior aspect of the spinous process, which was then removed using a Midas Rex drill (Fig. 2). This exposed the lateral recess on the contralateral side where residual lamina and ligamentum flavum could be resected using the drill, Kerrison punches, and curettes. The angle of approach was the same as that commonly undertaken during an open laminectomy, which allows undermining of the contralateral facets; thus, the anatomy is familiar to most spine surgeons. Satisfactory decompression of the lateral recess and foramina was achieved under direct visualization. Palpation of the pedicle and foramina, with a blunt ball-tipped nerve hook, ensured correct orientation and complete decompression (Fig. 3).

Depomedrol (80 mg) was instilled in the epidural space (unless duratomy had occurred) and bupivacaine 0.25% with epinephine 1:200,000 was infiltrated into the soft tissues. The incision was closed in layers by using Vicryl followed by placing Steristrips and a bioocclusive dressing or, more recently, Durmabond on the skin edge. The patients were encouraged to use ice postoperatively and were given only oral analgesic medication (usually hydrocodone). Patients were placed in a chair back brace for 6 weeks as a precautionary measure regardless of whether stability was demonstrated preoperatively on flexion–extension lateral radiographs. Physical therapy was initi-
ated at 6 weeks and thereafter increased activities were encouraged.

Sources of Supplies and Equipment

The METRx-MD system is manufactured by Medtronic (Memphis, TN). The basic questionnaire used to determine patients’ postoperative satisfaction was produced by PhDx (Albuquerque, NM). We obtained the Midas Rex drill (model TDQ 130D) from Medtronics, the Vicryl and Durmabond from Johnson and Johnson (Somerville, NJ), and the Steristrips from 3M Corporation (St. Paul, MN).

RESULTS

A total of eight stenotic/spondylolisthetic levels were decompressed in the eight patients. There were seven single-level procedures and one two-level procedure (in the patient with a second stenotic level unrelated to spondylolistheses): L4–5 in six, L3–4 in one, and L5–S1 in one patient. Two patients underwent concomitant discectomies at the index level. The mean operative time was 92 minutes/level, and the mean estimated blood loss was 33 ml. There was one duratomy that was not primarily repaired but covered with gelfoam. The patient was admitted for 48 hours of bedrest and did not experience adverse consequences. There were no neurological injuries and no infections.

Preoperatively stenosis was severe in five patients, moderate/severe in two, and moderate in one. Postoperatively stenosis was absent in five, mild in two, and mild/moderate in one. The five patients in whom no residual stenosis was observed postoperatively, preoperative stenosis was severe in two, moderate/severe in two, and moderate in one patient. In the two cases in which postoperative stenosis was mild, it had formerly been graded as severe. The postoperative mild/moderate had been severe stenosis preoperatively (Fig. 4). One patient has required a subsequent surgery for a herniated nucleus pulposus that developed at a level different from the original surgically treated level. After a minimum 2-year follow-up period, no patient has required reexploration of the stenotic level or secondary fusion.

Degenerative spondylolisthesis (Grade I) was observed at eight different levels in the eight patients. Seven patients underwent pre- and postoperative flexion–extension radiography (in the eighth no increase in subluxation was demonstrated on her postoperative MR imaging study). Abnormal motion in the sagittal plane was observed on the preoperative x-ray films in three patients. No increase in the degree of subluxation or the amount of motion was evident on postoperative x-ray films in any patient.

Analysis of the postoperative responses in the questionnaire revealed that 88% of patients thought it was definitely or mostly true that they could do the things they thought they would be able to do postoperatively and 63% thought it was definitely or mostly true that, all things considered, they would have the surgery again (Fig. 5). At the time of the postoperative interview, 81% of patients required no pain medications for back pain and 88% required no pain medications for leg pain. The mean preoperative VAS pain score was 7.6 and the average postoperative VAS pain score was 2 (Fig. 6).

DISCUSSION

Many authors have challenged the traditional treatment of spinal stenosis in which wide laminectomy and partial or complete facetectomy was performed. A variety of less extensive resections have been proposed in an attempt to preserve normal spinal anatomy.3,7,14,18,20,24,27 Although the goal of limited resection is to lessen the risk of postoperative spondylolisthesis, it is important not to compromise the neural decompression in one’s effort to be minimally invasive. The primary goal of the procedure is to obtain an adequate decompression of the neural elements. An ad-
ditional benefit of a minimally invasive procedure may be reduction of postoperative pain and disability and a decrease in hospital lengths of stay and thereby treatment costs.

The biomechanics of the normal spine have been extensively studied. The tendency for anterior subluxation to occur is resisted by multiple spinal elements. The facet joints have been shown to resist 33% of the shear forces, with the disc resisting 67%. The supra- and interspinous ligaments resist 19% of flexion forces, with the facet capsular ligaments resisting 39% and the disc resisting 29%. Adams and Hutton have also suggested that the muscular attachments to the posterior arch and the insertions of the muscular slips on the facet capsule brace the facets, improving their ability to resist displacement. The muscular and truncal soft-tissue contributions to flexion resistance are critical because the trunk-induced force exerted on the spine in flexion is greater by twofold than that required to injure the facet joints, which would fail if unaided by other supporting tissues. The supra/interspinous ligamentous complex has the greatest mechanical advantage because it is farthest from the axis of rotation. It is also the first to fail in flexion. In an anatomical study, Rissanen found that 20% of adult spines sustained ruptures of the ligament complex and many specimens had tears in the attachments to the spinous processes. This is an anatomical verification of the biomechanical results.

Cusick, et al., have conducted a biomechanical study in which they sequentially sectioned the posterior ligaments and facets and used a two-motion segment model. They noted the importance of the intact motion segment in stabilizing the altered segment, which more closely simulated the clinical situation than a single motion segment model. Although other authors of biomechanical studies have shown that the posterior ligaments make only a small contribution to overall stability, once the facet joints and the facet capsule have been altered surgically the relative contribution of the posterior ligaments to stability probably increases. The importance of the supra/interspinous ligament complex was emphasized. They progressively surgically altered the lumbar facet complex and found that the effects were controllable until the supra/interspinous ligaments and associated residual tendinous, midline muscle, and fascial attachments were violated. Their experimental model closely mimicked the postsurgical status evident in patients, and it stressed the contribution of the entire posterior musculoligamentous complex in resisting development of postoperative spondylolisthesis. Nevertheless, the rationale that saving as many of these elements as possible during the decompression may limit the

Fig. 5. Bar graph demonstrating patient satisfaction postoperatively.
development of iatrogenic spondylolisthesis remains controversial.3,9,19,20,29 Spondylolisthesis has been regarded as a contraindication to simple decompressive surgery, with many authors believing that concomitant fusion is indicated.3,9,13,15 The incidence of postoperative spondylolisthesis has been reported to range from 0 to 100%, with the common range being 10 to 12%.13 Johnsson, et al.,15 found a 56% incidence of increased postoperative subluxation in their patients in whom preoperative spondylolisthesis was documented. In their patients with degenerative spinal stenosis they reported a postoperative subluxation rate of 32%. Mullin, et al.,17 have found that patients with postoperative spinal instability tended to fair more poorly clinically with a lower ambulatory status. In our small group of patients, in those with preoperative spondylolisthesis increased postoperative subluxation did not occur. This may be the result of increased preservation of normal osseous, ligamentous, and muscular architecture when a minimally invasive procedure is performed. Thomas, et al.,24 found no significant correlation between spondylolisthesis and poor results. Although our population size was small, 81% with spondylolisthesis reported that they would definitely undergo surgery again for the same condition. Their mean VAS pain score was 7.6 preoperatively and 2 postoperatively.

Minimally invasive procedures have increasing application in spinal surgery. Our results demonstrate the feasibility of performing unilateral approach minimally invasive bilateral decompression for spinal stenosis associated with degenerative spondylolisthesis. The technique has evolved from multiple previously described techniques and is now performed in conjunction with placement of METRx-MD instrumentation. Satisfactory decompression was achieved in all patients (Fig. 4). Significant stenosis of up to 45% has been found in asymptomatic patients.15 The development of acquired spinal stenosis is an incremental process; none of our patients was symptomatic or without at least a moderate (third-degree) stenosis. Complete decompression may not be necessary to achieve symptomatic relief as has been previously suggested by Aryanpur and Ducker. Thomas, et al.,25 have reported a statistically significant increase in dural sac size after laminotomy or laminectomy but no statistical relationship between the extent of decompression and clinical outcome. It may only be necessary to bring the patient below a symptomatic threshold, which in our cases appeared to be moderate stenosis, to achieve a good clinical result.

Discectomy was performed in two patients with concomitant disc herniations. There has been concern that disruption of the annulus fibrosus might increase the risk of iatrogenic spondylolisthesis. Hopp and Tsou13 performed disc excision in half of their 344 patients and found no relationship between this surgery and postoperative vertebral instability. In our two patients no postoperative progression of the subluxation occurred.

The procedure described herein can be accomplished with reasonable operative times (mean 92 minutes) and minimal blood loss (mean 33 ml). Patient discomfort related to this muscle-dilating approach is such that most patients return home the same day. Although general anesthesia was induced in all patients, which is usually the patient’s preference, spinal anesthesia has been successfully used since this series was collected and can be induced when desired or medically indicated.

In a metaanalysis of the literature on spinal stenosis, Turner, et al.,29 found that good to excellent surgery-related outcomes varied from 26 to 100% (mean 64%). We defined a good outcome as one in which the patient felt, in the follow-up interview, that it was definitely or mostly true that he/she was helped by the surgery and a bad outcome as one in which the patient felt he/she did not know or felt it was mostly or definitely false that he/she was helped by the surgery. The generalizability of our outcomes is limited because this study covers a small cohort of patients and because of only short-term follow-up interview results (4–7 months). The good outcomes ranged from 63 to 88% (Fig. 5), in line with other series. The VAS pain scores decreased substantially after the surgical procedure. The mean preoperative VAS was 7.5, whereas the mean postoperative VAS score was 2 (Fig. 6).

The feasibility and success in this preliminary group of patients have encouraged us to continue with this procedure. A prospective study in a larger cohort will be necessary to answer the questions raised by this preliminary study. Does this minimally invasive surgical approach to spinal stenosis offer benefits in structural integrity, iatrogenic spondylolisthesis, operative efficiency, patient outcomes, patient satisfaction, and cost?

CONCLUSIONS

Minimally invasive bilateral decompression can be successfully performed via a unilateral approach in patients with acquired spinal stenosis associated with degenerative spondylolisthesis, in conjunction with placement of METRx-MD instrumentation. The procedure can be conducted on an outpatient basis, with reasonable operative times, minimal blood loss, and acceptable morbidity. Short-term clinical outcomes in this small series are simi-
lar to those reported in other series in which spinal stenosis was treated surgically.
