Dural arteriovenous fistulas (dAVFs) are acquired direct arteriovenous shunts that often drain into the dural venous sinus. Treatment options generally involve disrupting the abnormal vascular conduits by using a combination of modalities, including surgical disconnection, radiosurgery, and transarterial and transvenous embolization. Often these modalities provide only partial treatment of fistulous lesions, and thus the fistula recurs and symptoms result. The authors report on a novel surgical technique in which the involved venous sinuses are skeletonized and an interpositional dural substitute is placed between the disconnected sinus and native dura mater and over the pial surface adjacent to the sinus. The technique, which is demonstrated in an illustrative case, is intended to preserve native venous drainage and to prevent recruitment of new vascularization to the venous sinus postoperatively. The authors have not observed reconstitution of fistulas over areas treated with this technique, which offers the advantage of inhibiting vascular ingrowth (refistulization) while maintaining venous sinus patency.

KEY WORDS  • dural arteriovenous fistula  • dural substitute  • graft

Surgical Procedure

The goal of the operation is to physically interrupt arterial channels within the dura mater that directly enter the involved sinus(es). The initial dural incision is made approximately 2 to 3 mm from the edge of the sinus and is carried parallel to the sinus. Brisk bleeding from the cut dural edge can again occur over the length of the affected sinus and can be controlled with bipolar electrocautery or hemostatic clips, if necessary. A piece of dura (bovine pericardium cross-linked with glutaraldehyde, DuraGuard dural repair patch, Synovis) is tailored to fit between the available modalities,2 the risk of treatment failure is high, with failure rates of 11 to 100%, depending on the treatment modality used and the location and aggressiveness of the lesion.10

We here report on a novel technique in which an interpositional modified xenograft dural patch graft is placed between the sinus and the native dura mater after the skeletonization of sinuses. A graft is also placed over the pial surface to prevent fistulization. We believe that this technique might reduce the risk of recurrent dAVFs in the future by preserving cerebral venous drainage and thus reducing venous hypertension that promotes fistula development, and by introducing a physical barrier that may prevent recruitment of new vasculature.

Abbreviations used in this paper: AV = arteriovenous; dAVF = dural arteriovenous fistula.
cut edges of the native dura as demonstrated in Fig. 1. As opposed to other newer synthetic substitutes that eventually allow the ingrowth of native tissue, we prefer Dura-Guard because it is inert and essentially forms a barrier against the vascular ingrowth. Disconnecting the sigmoid sinus, especially the presigmoid dura, can be challenging but is achieved with adequate drilling of the surrounding bone. Disconnecting the transverse sinus from the tentorium is imperative, but suturing an interpositional graft is more difficult because of the physical constraints in this region. Finally, a piece of dural repair patch is placed on the brain itself to physically separate it from the sinus if there is concern about the development of pial fistulas.

Illustrative Case

History and Examination. This 28-year-old man presented with symptoms of intracranial hypertension, including constricted visual fields requiring optic nerve sheath fenestration, and several weeks of increasing audible bruit. One year earlier, he had sustained a transverse sinus thrombosis after an episode of dehydration, which was treated with anticoagulation therapy. His examination was remarkable for an audible bruit over the left temporal and suboccipital area and palpable feeding vessels over the suboccipital region. Results of an angiographic evaluation revealed an extensive dAVF involving the torcular herophili, the bilateral transverse sinuses, and the left sigmoid sinus. Feeding arteries emanated from the vertebral, occipital, auricular, middle meningeal, tentorial, and superficial temporal arteries. The left sigmoid–jugular junction was noted to be mildly stenotic, and retrograde flow from the left sigmoid and transverse sinus to the right transverse sinus was present. Cortical reflux was also noted (Fig. 2).

Treatment. The patient underwent embolization of the multiple feeding arteries, including those from the left occipital, left middle meningeal, and left superficial temporal arteries. The procedure resulted in marked improvement in venous flow, with resumption of antegrade flow in the left sigmoid and transverse sinuses, but feeding arteries from the posterior meningeal branch of the left vertebral artery and the left tentorial artery were still present.

Two days after embolization, the patient underwent surgical skeletonization of the bilateral transverse sinuses and posterior sagittal sinus with placement of an interpositional dural graft. Specifically, the patient’s transverse sinus on the left was skeletonized to the transverse–sigmoid junction superiorly, along the sigmoid to the jugular bulb inferiorly, and along the tentorium from the torcular herophili to the transverse–sigmoid junction. On the right side, skeletonization was performed to the transverse–sigmoid junction both superiorly and inferiorly. A postoperative angiogram demonstrated no remaining fistula over the region of disconnection (Fig. 3).

Posttreatment Course. The patient has been followed up for a period of 3 years with no evidence of new fistulization at the disconnected sites.

Note that in our experience with six patients, no demonstrable recurrence of fistulization has been observed over the region of inert graft placement (range of follow up 1 month–4 years).

DISCUSSION

We described a modification to Lucas and colleagues’9 technique of sinus skeletonization for the surgical treat-
ment of dAVFs with sinus drainage. This modification can be useful in preventing the recurrence of fistulas by imposing a mechanical barrier between native dura mater and the sinus while maintaining the patency of the involved sinuses. We demonstrated this procedure in a patient who tolerated it without surgical complication or recurrence of the fistula.

Current open surgical and endovascular treatments of dAVFs are focused on eradicating one (arterial or venous) or both sides of the fistula. Specifically, this process involves physically disconnecting the feeding arteries or obliterating or resecting the involved sinuses. Endovascular arterial embolization rarely results in permanent obliteration of fistulas and is now mostly used for palliation and as a preoperative aid.13 Sinus obliteration via a transvenous endovascular approach or combined with an open surgical approach has been proposed; however, its use has been tempered because it is only appropriate in cases in which the sinus is arterialized, it fails to maintain or restore normal venous drainage, and it can have significant complications including venous infarction and hemorrhage.3 Open resection of the affected sinus has also been performed.13 Additionally, only directly arterialized sinuses can be resected with adequate collateral venous drainage. The boundaries of resectable and unresectable sinuses can be difficult to ascertain intraoperatively, and venous infarction can result with the obliteration of normal sinus drainage. Radiosurgical obliteration of dAVFs is being used as a surgical adjunctive or primary treatment with some success. Although cure rates of up to 72% have

been reported, obliteration can take up to 2 years, during which time the patient is still at risk of hemorrhage.\textsuperscript{8,12} Finally, surgical skeletonization of the dural sinuses has been described as an effective tool in dealing with this disease process.\textsuperscript{6,9} However, simple interruption of the dura mater without placement of an interpositional graft may not provide an adequate barrier for revascularization, which has been witnessed in previous cases treated by the authors and others.

CONCLUSIONS

We reported on a technique for the treatment of dAVFs in which the affected sinuses are skeletonized and isolated with the placement of a dural interpositional graft. Thus far we have not observed reconstitution of fistulas over areas treated using this technique. The procedure offers the advantage of maintaining venous sinus patency, which may reduce the development of further venous hypertension and thereby decrease the pathophysiological impetus for the development of additional fistulas.
