A brief history of surgery for peripheral nerve sheath tumors

CIARAN J. POWERS, M.D., PH.D., AND ALLAN H. FRIEDMAN, M.D.
Division of Neurosurgery, Department of Surgery, Duke University Medical Center, Durham, North Carolina

The authors present a brief and selective history of surgery for peripheral nerve tumors to illustrate how the current understanding of the nature of disease influences the choice of surgical intervention. There was very little understanding of the anatomy and function of peripheral nerves in ancient times; consequently, surgical treatments for peripheral nerve tumors were based on the writings of authorities. The confusion between traumatic neuromas and genuine nerve sheath tumors coupled with the belief that manipulation of a peripheral nerve might be lethal to the patient stifled the development of surgical techniques for the management of nerve tumors in the 18th and 19th centuries. It was not until the 20th century, with an increased understanding of the microscopic anatomy of nerve sheath tumors, that efficacious surgical treatments for these diseases were developed. Continued advances in the understanding of the biology of these tumors will continue to impact their surgical management.

KEY WORDS • history • peripheral nerve sheath tumor • surgery

Ancient History: Tendons and Nerves

It is difficult to interpret the writings from antiquity concerning peripheral nerve tumors, and often impossible to correlate the descriptions of diseases in general in a modern medical textbook with those mentioned in ancient writings. Furthermore, the descriptions of peripheral nerve lesions in ancient writings are predominantly about traumatic injuries; peripheral nerve tumors were simply too rare to have generated a significant amount of literature. Consequently, a review of the ancient literature reveals only vague references to peripheral nerve tumors. The ancient Greeks did not usually perform dissections of the human body, and their understanding of anatomy was quite rudimentary. There seems to have been confusion regarding the structural and functional differences between nerves and tendons. In translations of Homer’s Iliad, the word “περιονοτέ” has been interpreted to mean either “tendon” or “nerve,” and is translated accordingly based on its context. Furthermore, because spontaneous illnesses were thought to be the will of the gods, management was directed more towards the divine rather than some physical intervention. This is in contradistinction to the ancient management of traumatic injury, the cause of which was obvious and the treatment more pragmatic.

The Hippocratic writings (circa 460–375 BC) reveal a slightly more sophisticated understanding of nerves themselves, although there was still confusion over the difference between tendons and nerves. In his commentary on translating the Hippocratic writings, The Nature of the Child and The Heart, I. M. Lonie describes the ambiguity of words used to describe nerves and tendons. Based on the book of Aphorisms, it is clear that the Hippocratic authors were aware that nerves do not spontaneously regenerate after resection. In Section VI of Aphorisms, the authors state that “division of bone, cartilage, nerve, the delicate
part of the jaw, or of the foreskin is not followed by growing and joining together again.” This concept is repeated in Section VII, with the statement that “bones, cartilages and nerves, when divided, will not reconstitute themselves.”17 The Hippocratic writings also contain the idea that “cold is bad for nerves, heat is good,” a concept put forth in Aphorisms Section V.17 This provided the basis for a medical management of nerve injury: if the cause of nerve dysfunction was cold, heat might improve nerve function.

The ancient Greek author Herophilus (circa 335–280 BC) contributed to a greater understanding of peripheral nerves and their functions through dissections of human cadavers. He distinguished nerves from tendons and traced their origin back to the spinal cord.7 Unfortunately, his writings were lost in the fire of the library at Alexandria in 272 AD.

Galen of Pergamon (129–200 AD) based his understanding of peripheral nerves and their function on anatomical dissections, often of pigs and apes. He wrote detailed descriptions of the anatomy of peripheral nerves from the spinal cord out to the small digital nerves. Galen believed that once they were divided, peripheral nerves would not regenerate,18 and held that a wounded nerve in continuity with the brain would cause convulsions. Galen recommended an incision of ground earthworms to treat nerve injury rather than surgical repair.30

The ninth century Islamic physician Rhazes wrote extensively on neuroanatomy and was one of the first writers to assign separate motor and sensory functions to nerves. In Kitab al-hawi Fi Al-Tibb,31 Rhazes described how cross-sectioning a nerve leads to a loss of function while longitudinal sectioning does not:

You have to be knowledgeable of the nerves that serve each organ. Some of the nerves are for sensation; some of other nerves have motor function. The nerve that innervates the skin has a sensory function whereas the nerve that goes to tendon (muscle) has a motor function. The nerve function is abolished when the nerve is totally sectioned from a contusion, or compression, edema or tumor or from a severe cold that affects it. However, nerve lesions from edema, compression or cold may be reversed when the cause is treated. If there is a section in the body of the nerve as its middle part (cross section), paralysis of organs in that area occurs; if the nerve has longitudinal section (no loss of continuity of the nerve) organs are not damaged at all. Always go, in case of loss of sensation or movement by an organ, to the origin of the corresponding nerve, if it is cold warm it, if it is edema put some medication; if there is section of the nerve (total loss of nerve continuity) there is no therapy.

Rhazes echoed the Hippocratic idea of using heat to improve nerve dysfunction caused by cold. However, in cases in which the nerve was completely divided, Rhazes had a nihilistic perspective on treatment, and did not introduce any surgical options. Thus, although there was gradual advancement in the scientific understanding of peripheral nerves in ancient times, this progress did not lead to the rational surgical management of nerve injury or disease.

Eighteenth and Nineteenth Centuries: Traumatic Neuromas and Nerve Tumors

The idea that nerves could regenerate was not established until the end of the 18th century.2 Working in Hunter’s laboratory in 1776, Cruickshank severed the vagal nerve in a dog; 2 weeks later he severed the contralateral vagal nerve, and the dog died. When he examined the site where the first vagal nerve had been severed, he noted a white substance which he did not think was scar tissue, but possibly regenerating nerve tissue. When he increased the time interval between severing the first and the contralateral vagal nerve, the animals survived. His work was presented to the Royal Society as evidence that nerves could regenerate but because his thesis rejected 1700 years of belief, it was rejected for publication. Nineteen years later, Haighton7 repeated these experiments. He cut one vagal nerve and some weeks later cut the second. After the dog was shown to have survived, Haighton went back and recut the first vagal nerve; the dog subsequently died. After this series of experiments, both Cruickshank and Haighton’s manuscripts were published in 1795.

Most reports of nerve tumors in the 17th century concerned the swellings found on the ends of transected nerves, as is described by Lower in 1669.39 Odier of Geneva4 first applied the term “neuroma” to tumors formed by diseased enlargements of nerves. One of the first true descriptions of the surgical management of a PNST can probably be credited to Cheselden in 1741. In The Anatomy of the Human Body, Cheselden1 described a tumor that occupied the center of a “cubital” nerve, displacing the nerve fibers to the periphery. This seems to be a description of a schwannoma, but there is not enough clinical or histological information to draw this conclusion definitively. Despite recognizing the distinction between the nerve fibers and the tumor tissue itself, Cheselden seems to have excised the tumor en bloc with the nerve. In his extensive review of peripheral nerve tumors, Woods noted that “a number of nervous fasciculi, sometimes a good deal flattened can be traced, in a perfect state of continuity, running over its surface, to be connected below with the trunk of the nerve.” As is typical of any major scientific advancement, new ideas that contradicted the dogma of the time were overlooked, only to be rediscovered later. Home recognized that some nerve tumors might be dissected free from the nerve fibers. In 1800 Home32 described witnessing Hunter perform an en bloc resection of a tumor of the musculocutaneous nerve. Home examined the specimen in the laboratory and realized that the tumor could easily have been removed while keeping the parent nerve intact, concluding that en bloc resection of nerve tumors was unnecessary. Home subsequently put this theory to the test when he encountered a patient with an axillary nerve tumor. In his article he described incising the tumor and enucleating it with finger dissection. Unfortunately, the patient died on the postoperative Day 7, and at autopsy no cause of death was revealed other than inflammation at the operative site. Subsequently, it was considered too dangerous to dissect a tumor from a peripheral nerve, and both Swan44 in 1820 and Wood40 in 1829 discouraged the practice. Wood speculates that the death may perhaps be ascribed more to the general constitutional attention caused by the inflammation excited by the important parts seated in the axillary than from anything peculiar in the nervous connection of the tumor. It is worth consideration, at least, how far the result might have been different, if it had been possible to have removed the tumor along with the cyst, by the more simple operation of dividing the affected nerve in two places.

Wood echoed the practice of his time of treating periph-
eral nerve tumors by “extirpation of the diseased part alone, and when essentially necessary to have recourse to removal of the affected limb.”

As there was confusion in distinguishing between traumatic neuromas and nerve tumors, the approach of en bloc resection was applied to the management of both. In addition, many authors believed that inflammation of a peripheral nerve could be fatal to the patient. In 1813, Denmark treated a patient with a painful neuroma of the radial nerve from a musket ball wound with amputation of the arm. It was not until he examined the specimen and found a piece of the bullet in the neuroma that he questioned if the procedure had been too radical. Commentators on this case appear to have concluded that Mr. Denmark’s case was simply a typical nerve tumor that resulted from trauma.

As late as 1855, James Syme reported treating peripheral nerve tumors with amputation. In The Lancet, Syme described three patients with peripheral nerve tumors and their management with amputation of the affected limb. Syme’s strategy for managing these tumors is articulated clearly in his description of his first patient, a 43-year-old farm laborer who had “a swelling of the forearm, on the palmar side, a little above the wrist, about as large as a hen’s egg.” It is unclear if this was a traumatic neuroma or a genuine nerve tumor, as the patient had suffered blunt trauma to the area several years previously. Syme assessed the patient as having a neuroma of the median nerve and wrote: “I think before resorting to removal of the hand, an attempt should be made to dissect out the tumor; but the chance of success in accomplishing this being very small, the patient should be made to dissect out the tumor; but the chance of success in accomplishing this being very small, the patient has given his consent to amputation if it should prove necessary.” Unfortunately, at the time of operation Syme found the tumor “too intimately connected with the surrounding parts to admit of removal without amputation” and he amputated the patient’s hand at the midforearm. On examining the specimen, he found “the tumor itself was of roundish form, of yellow-white color, and pretty firm consistency. The fibers of the nerve were beautifully expanded over its surface.”

Although Odier first used the term “neuroni” in 1811 to describe deep-seated, circumscribed nerve tumors, many other authors applied it indiscriminately to both primary and metastatic tumors involving nerves, as well as to traumatic neuromas. Between 1829 and 1842, Cruveilhier used the same term in his illustrations of peripheral nerve tumors and the swollen ends of nerves in amputation stumps. In 1849 R. W. Smith used the same term in his illustrations of peripheral nerve tumors of the peripheral nerves into “true” and “false” neuromas. The “true” neuromas contained both nerve fibers and elements of the nerve sheath, while “false” neuromas contained only the elements of the nerve sheath. This allowed clinicians to distinguish between traumatic neuromas and true peripheral nerve shear tums.

In descriptions of the management of nerve tumors, some authors began to apply the increasingly sophisticated understanding of nerve response to traumatic injury and the role of reestablishing continuity to a transected nerve. As noted by Walker, Michion in 1849 and Nelaton in 1863 described the management of tumors of the sciatic and median nerves, respectively, with en bloc resection followed by reappraisal of the nerve ends. Nelaton reported removing a neuroma of the median nerve and reapproximating the cut nerve ends with two silver wires. He reported that on Day 7 postoperatively the patient could move all of her fingers and oppose her thumb. This report led surgeons to believe that the median nerve regained function in only 7 days. Amputation as the primary treatment for PNSTs became increasingly less popular, and in 1887 Krause advocated simple excision for well-encapsulated nerve tumors, reserving amputation for recurrent nerve tumors.

**Twentieth Century: Schwannomas and Neurofibromas**

Debate over the cell of origin of PNSTs began in the late 19th century. In 1869, Generisch first proposed that “false” neuromas (using Virchow’s nomenclature) arose from Schwann cells. Von Recklinghausen hypothesized in 1882 that peripheral nerve sheath tumors were derived from endoneurium. Based on his observations of the appearance of the cells under light microscopy, in 1910 Verocay argued that PNSTs arose from Schwann cells. The argument over the cell of origin for PNSTs continued through the 20th century. Masson argued that “the fundamental element of encapsulated neurinomas (schwannomas) is structurally identical with the syncytium of Schwann when that syncytium is undergoing autonomous proliferation.” On the other hand, in his review of nerve sheath tumors, Wilder Penfield argued the opposite:

> These tumors do not contain nerve fibers. The mistaken belief that they did do so led Verocay to call them neurinomas. They do not contain neuroglial elements, to the best of my belief after exhaustive study by means of special neuroglia methods. The type cell is not the Schwann cell but the connective tissue perineurial and endoneurial cell, as shown by the following facts. The tumor cells form fibroglia, collagen fibrils and elastic tissue. The outstanding histologic characteristic of these tumors is the presence in them of long parallel hair-like fibrils which stream together like hairs in a brush. They are not nerve fibrils. They are the architectural support without the nerve. They are reticulin fibrils staining with the same specific stains used for reticulin elsewhere...the Schwann cells, which seem to be analogous to neuroglia, could hardly be expected to form fibrils of this sort which bear no resemblance to neuroglia fibrils.

In 1940, Margaret Murray and Arthur Stout defined the arguments for and against Schwann cells as the origin of nerve sheath tumors:

Since the description by Verocay in 1908 of the specific nerve sheath tumor which he named neurinoma, two opposing views of its cellular origin have prevailed. One, represented by the work of Nageotte, and of Masson, is based on the study of the morphology and physiology of normal nerve sheaths under various experimental conditions. By comparing the histology of these tissues with that of the tumors, these workers feel that they have proved that the tumor originates from the sheath of Schwann. They therefore give it the name schwannoma, or peripheral glioma. The opposing opinion, represented by the work of Mallory and of Penfield, emphasizes mainly the study of the extracellular components of these tumors, and rests on the assumption that collagen and reticulin can be formed only by cells of mesodermal derivation. Since the tumors contain schwann cells...
considerable collagen and reticulin, this line of reasoning induces the conclusion that the tumors are derived from the endoneural or perineural components of the nerve sheath, and the term perineural fibroblastoma is adopted.

Murray and Stout went on to culture normal nerve sheath and nerve sheath tumor cells in the laboratory. They found that the morphological characteristics of outgrowing cells was the same in both cultures and offered very compelling evidence that Schwann cells were the neoplastic cells in their tumor specimens.21

Further investigation into the histological characteristics of PNSTs revealed the presence of two different types of tumors: schwannomas and neurofibromas. As articulately described by Harkin and Reed1 in 1969,1 a schwannoma “begins as a confined local growth that compresses the nerve around its periphery as it expands,” while a neurofibroma is “composed of a tortuous plexus of Schwann cell cylinders and axons.” Electron microscopy performed in the early 1990s confirmed the involvement of Schwann cells in the pathogenesis of schwannomas, yet there were several different cell types seen in neurofibromas, and identification of the actual tumor cell remained elusive.29

Advances in molecular and cellular biology have generated significant evidence indicating that Schwann cells are the cell of origin for both schwannomas and neurofibromas.13,20,26,28,29 Using immunohistochemical analysis, Stefansson and colleagues21 in 1982 reported that S100, a protein found normally only in Schwann cells, is also present in the predominant cell type of both plexiform and cutaneous neurofibromas. Furthermore, in 1990 Sheela et al.29 found that neurofibroma Schwann cells promote angiogenesis and are invasive in the chick chorioallantoic membrane model, yet neurofibroma fibroblasts neither promote angiogenesis nor are invasive.

The current model (reviewed by Gottfried et al.18) holds that in both schwannomas and neurofibromas the tumor cell is a Schwann cell completely lacking expression of the NF1 gene. The NF1 protein functions as a tumor suppressor by promoting the inactivation of the signal transduction protein Ras. Ras is activated when G protein–coupled receptors replace GDP with GTP bound to Ras. Ras inactivation is caused by hyrolysis of GTP to GDP, an enzymatic process that is inherent in Ras but occurs at a slow rate. Neurofibromatosis Type 1 protein promotes the autohydrolysis of GTP to GDP in Ras, inactivating it. In schwannomas it is only the Schwann cell that is lacking the NF1 protein and, although it does secrete mitogens capable of functioning as both autocrine and paracrine growth factors, the supporting cells are otherwise normal. On the other hand, in patients with neurofibromatosis all of the supporting cells are haploinsufficient for NF1 and have a relative Ras hyperactivity, leading to increased proliferation in response to growth factors secreted by the tumorogenic Schwann cells.

A better understanding of the distinction between schwannomas and neurofibromas made a significant difference in their surgical management. Although schwannomas can usually be separated from the parent nerve and removed, it is often very difficult to do the same with neurofibromas. In the 1970s and 1980s, authors did not recommend attempted resection of neurofibromas,24 but advocated en bloc resection of the tumor and nerve with reconstruction.10,23 However, as described by Donner et al.6 in 1994, nonplexiform neurofibromas often only involve a few fasicles and with careful technique may be resected while sparing the parent nerve. Donner and associates5 reviewed their surgical experience in 263 patients with nerve sheath tumors and concluded:

With the exception of the rare plexiform tumors, benign nerve sheath tumors should be considered resectable; however, neurofibromas have been believed by many to be unresectable due to a misleading histological appearance that suggests invasiveness. Our results indicate that neurofibromas as well as schwannomas can be removed, even from large nerve trunks, with an acceptable risk of injury to the nerve. Excision of solitary neurofibromas is possible, especially if an infrafacial approach at both poles of the tumor and repeated NAP (nerve action potential) recording are used. Fascicles entering and leaving the tumor substance are usually nonfunctional, and their division usually does not lead to increased neurological deficit.

Conclusions

This brief review of surgery for peripheral nerve tumors illustrates how advances in the understanding of a disease have a profound impact on its surgical management. The ancient Greeks do not seem to have understood the function of nerves and so they did not describe peripheral nerve tumors, let alone develop any surgical intervention to treat them. In the 18th century, given the concern over life-threatening inflammations after manipulation of a nerve, the accepted practice was to remove the tumor en bloc with the parent nerve, or to amputate the affected limb. By the 19th century, with advances in nerve reapproximation, the goal of surgery was en bloc resection, followed by nerve anastomosis. In the 20th century, our understanding of the microscopic and structural differences between schwannomas and neurofibromas has made the practice of dissecting PNSTs from the parent nerve accepted. Today, further advances in our understanding of the molecular and genetic pathogenesis of PNSTs may hold even more rational approaches to the management of these tumors, perhaps even without surgery.
