Quinoline-based antimalarial drugs: a novel class of autophagy inhibitors

Encouse B. Golden, MD, PhD; Hee-Yeon Cho, PhD; Florence M. Hofman, PhD; Stan G. Louie, PhD; Axel H. Schönthal, PhD; and Thomas C. Chen, MD, PhD

OBJECT Chloroquine (CQ) is a quinoline-based drug widely used for the prevention and treatment of malaria. More recent studies have provided evidence that this drug may also harbor antitumor properties, whereby CQ possesses the ability to accumulate in lysosomes and blocks the cellular process of autophagy. Therefore, the authors of this study set out to investigate whether CQ analogs, in particular clinically established antimalaria drugs, would also be able to exert antitumor properties, with a specific focus on glioma cells.

METHODS Toward this goal, the authors treated different glioma cell lines with quinine (QN), quinacrine (QNX), mefloquine (MFQ), and hydroxychloroquine (HCQ) and investigated endoplasmic reticulum (ER) stress–induced cell death, autophagy, and cell death.

RESULTS All agents blocked cellular autophagy and exerted cytotoxic effects on drug-sensitive and drug-resistant glioma cells with varying degrees of potency (QNX > MFQ > HCQ > CQ > QN). Furthermore, all quinoline-based drugs killed glioma cells that were highly resistant to temozolomide (TMZ), the current standard of care for patients with glioma. The cytotoxic mechanism involved the induction of apoptosis and ER stress, as indicated by poly(ADP-ribose) polymerase (PARP) cleavage and CHOP/GADD153. The induction of ER stress and resulting apoptosis could be confirmed in the in vivo setting, in which tumor tissues from animals treated with quinoline-based drugs showed increased expression of CHOP/GADD153, along with elevated TUNEL staining, a measure of apoptosis.

CONCLUSIONS Thus, the antimalarial compounds investigated in this study hold promise as a novel class of autophagy inhibitors for the treatment of newly diagnosed TMZ-sensitive and recurrent TMZ-resistant gliomas.

KEY WORDS glioma; chloroquine; antimalaria compound; autophagy; endoplasmic reticulum stress

Glioblastoma multiforme (GBM) is a malignant brain tumor associated with a poor prognosis. Temozolomide (TMZ) is the conventional chemotherapy for patients with GBM; however, patients usually develop TMZ resistance and succumb to death. Chloroquine (CQ) in combination with conventional GBM therapy recently demonstrated the ability to prolong median survival from 11.4 to 25 months in patients with GBM. The mechanism by which CQ enhances conventional GBM therapy is not well understood.

Quinoline-based antimalarial (QBA) compounds are weak bases that accumulate in the acidic food vacuoles (AFVs) of Plasmodium falciparum parasites. The chemical structures of several QBAs are displayed in Fig. 1. Chloroquine, the prototypical antimalarial compound, interferes with ferrirrotoporphyrin IX detoxification in the AFVs of P. falciparum, thereby causing parasite death. In addition to AFVs, CQ has been shown to accumulate in the acidic lysosomes of tumor cells, thereby disrupting autophagy.
The AFVs of the malaria-causing parasite, *P. falciparum*, catabolize erythrocyte-derived hemoglobin to provide bioenergetic support for parasite growth and replication.18,26 Similarly, tumor cell lysosomes degrade damaged organelles or bulk proteins for amino acid and energy recycling via the autophagy pathway.8

Quinoline-based antimalarial compounds, such as CQ, hydroxychloroquine (HCQ), quinine (QN), mefloquine (MFQ), and quinacrine (QNX), are mainstay therapies that effectively kill *P. falciparum* parasites. Chloroquine, a commonly prescribed QBA that harbors weakly basic properties, traverses erythrocyte and *P. falciparum* cellular membranes down a pH gradient to accumulate inside AFVs and disrupt heme detoxification, thereby causing parasite death. Hydroxychloroquine has antimalarial activity similar to that of CQ; however, since HCQ has a lower associated risk of ocular toxicity, it is clinically preferred over CQ when high doses are necessary for the treatment of malaria.17,27 Quinine was the initial QBA isolated from tree bark powder of the *Cinchona* species.40 A 3- to 7-day regimen of QN has rates of efficacy ranging from 54% to 95% against uncomplicated malaria caused by *P. falciparum* throughout different regions in the world.5 Mefloquine and QNX have been shown to be efficacious in CQ-resistant malaria.7,11,28,33,41 Quinine, MFQ, and QNX have demonstrated the ability to penetrate the blood-brain barrier; therefore, QN and MFQ are effective-ly used to treat malaria-causing parasites that have entered the central nervous system.3,5,21,22,32

In addition to targeting the AFVs of *P. falciparum*, CQ has recently received attention for its antitumor effects, where it was shown to accumulate in the lysosomes of tumor cells, blocking autophagy and preventing the degradation of autophagosomal content. Moreover, we have recently examined the use of MFQ in breast cancer.35

Since QBAs possess the unique ability to accumulate in the AFVs of *P. falciparum* in various clinical conditions, we set out to determine whether these compounds have antitumor properties similar to those of CQ, including the ability to accumulate in lysosomes and block autophagy. Our data here showed that QBAs induced higher levels of CHOP/GADD-153 (an endoplasmic reticulum [ER] stress proapoptotic protein) as well as apoptosis in vitro and in vivo in U87MG subcutaneous implants. These data indicate that QBA compounds are a novel class of clinically useful autophagy inhibitors that accumulate in lysosomes and block autophagosome degradation, thereby activating ER stress and induced apoptosis in tumor cells.

**Methods**

**Reagents**

Chloroquine, MFQ, QNX, QN, and HCQ were all purchased from Sigma (St. Louis, MO). The CQ, HCQ, QNX, and QN were dissolved in ultrapure water at 100-μM concentrations. Mefloquine was dissolved in dimethyl sulfoxide (DMSO) at 100-μM concentrations. All compounds were stored at −20°C.

**Cell Lines and Culturing**

Human glioma cell lines (LN229 and U251) were kindly supplied by Dr. Frank Furnari. The U87 glioma cells were purchased from American Type Culture Collection. Glioma cells were propagated in DMEM (Cellgro) supplemented with 10% fetal bovine serum. All cell lines were grown in 100 U/ml penicillin and 0.1 mg/ml streptomycin in a humidified incubator at 37°C, 5% CO₂ atmosphere.

**In Vivo Subcutaneous Glioma Rodent Model**

All animal protocols were approved by the University of Southern California Department of Animal Resources, and animals were maintained according to approved guidelines. Tumor cells (2 × 10⁵) were injected subcutaneously into the right flank of athymic nude mice. After tumors were palpable, animals were treated with vehicle or drugs for 24 or 48 hours. Subsequently, the animals were euthanized, and tumor tissues were harvested and prepared for immunohistochemistry (IHC) staining, as described below.

**MTT Assay**

The MTT assay, a measure of cell viability, was per-
Quinoline analogs inhibit autophagy

Preparations of the cell lysates and determination of the protein concentration were performed as previously described. Lysate (50 μg) from each sample was run in parallel. Primary antibodies were purchased from Cell Signaling Technologies or Santa Cruz Biotechnology Inc. and were used according to the manufacturers’ instructions. Blocking buffer and fluorescent-conjugated secondary antibodies were purchased from LI-COR Biosciences and used according to protocols supplied by the manufacturer. The membranes were scanned and analyzed with the Odyssey Infrared Imaging System (LI-COR Biosciences). Immuno-FLA + SPOT camera, model 1.4.0, operated with Spotted Advanced Digital Imaging software version 4.0.8 (Diagnostic Instruments) and saved in a 12-bit grayscale format with 1600 × 1200 active pixels.

Immunofluorescent and IHC Staining

In order to determine whether the cytotoxic effects of CQ and its quinoline-based analogs could overcome TMZ resistance in glioma cells, we treated U251 and TMZ-resistant U251 (U251-TMZ) cells with CQ, QNX, MFQ, and QN in parallel MTT assays (Fig. 2C). We found that U251 and U251-TMZ cells respond to the QBA compounds at similar doses. The U251 cells’ IC50 for CQ, MFQ, and QNX was 40, 15, and 8 μM, respectively; the U251-TMZ cells’ IC50 for CQ, MFQ, and QNX was 40, 12, and 10 μM, respectively. Similar results were obtained for LN229/LN229-TMZR and U87/U87-TMZR tumor cell pairs (data not shown). The LN229 cells’ mechanism for resistance has been established to be DNA mismatch repair deficiency. Resistant U251 cells are associated with overexpression of base excision repair proteins. The TMZ-resistant U251 cells were also tested using the long-term colony-formation assay (CFA; Fig. 2D). Data in the present study showed that in the CFA, 100 μM of TMZ reduced the percentage of colonies formed in U251 cells by approximately 95%; in contrast, 100 μM of TMZ reduced the percentage of colonies formed in U251 cells by approximately 95%; in contrast, 100 μM of TMZ reduced the percent...
of colonies formed in U251-TMZ\textsuperscript{R} by only approximately 25%. We confirmed TMZ resistance in the LN229-TMZ\textsuperscript{R} and U87-TMZ\textsuperscript{R} cells with CFA and long-term MTT assays (data not shown). These results showed that QBAs are cytotoxic to TMZ-sensitive and TMZ-resistant glioma cells, regardless of the p53 and PTEN status or the mechanism of resistance to TMZ.

**Autophagosome Accumulation and Induction of ER Stress–Induced Apoptosis by Chloroquine**

Chloroquine blocks autophagy in tumor cells; however, the mechanism of this cell death pathway is not well understood. To investigate CQ’s mechanism of action, we treated U251 cells with CQ (50 \mu M); after 48 hours, the CQ-treated U251 cells (Fig. 3A, left 2 columns) displayed an accumulation of cytoplasmic vacuoles, as compared with untreated controls. To identify the CQ-induced vacuolar accumulation, the CQ-treated cells were stained with LC3B, an autophagosome marker (Fig. 3A, right 4 columns). Staining revealed an increase in the intensity and amount of LC3B accumulation in the CQ-treated U251 cells.

To confirm the presence of autophagosome accumulation in CQ-treated glioma cells, conversion of the cytoplasmic form of LC3B (LC3B-I) to the autophagosomal membrane-bound form (LC3B-II) was evaluated using LN229 glioma cells (Fig. 3B). Chloroquine increased the conversion of LC3B-I to LC3B-II. Furthermore, CQ treatment caused an increase in the induction of CHOP/GADD-153 (an ER stress proapoptotic protein) expression.
Quinoline analogs inhibit autophagy and cleavage of the DNA repair enzyme poly(ADP-ribose) polymerase (PARP; PARP cleavage is an apoptosis marker; Fig. 3B).

To determine whether CQ can inhibit isolated 20S proteasomes at relevant cytoplasmic concentrations, isolated proteasomes were treated with increasing concentrations of CQ from 0 to 40 μM. Data indicated that CQ can stimulate proteasome activity approximately 60% (Fig. 3C); however, treatment with lactacystin (2.5 μM), a proteasome inhibitor, showed proteasome activity was reduced to approximately 90%. Thus, CQ induces apoptosis by blocking the degradation of autophagosomes, but not as a result of proteasome inhibition.

Blocking Autophagy and Inducing Apoptosis in Glioma Cells

Based on information that CQ induces apoptosis by blocking autophagy, we analyzed whether the other QBA compounds can function in a similar manner. U251 cells were treated with increasing concentrations of CQ, QN, HCQ, QNX, and MFQ and were tested for the conversion of LC3B-I to LC3B-II, induction of CHOP/GADD-153, and cleavage of PARP. The U251 cells treated with increasing concentrations of QBA compounds were able to mimic the cytotoxic effects of CQ (Fig. 4).

Each compound increased the conversion of LC3B-I to LC3B-II, the levels of polyubiquitinated proteins, the induction of CHOP/GADD-153, and the cleavage of PARP, in direct correlation with the drug’s ability to reduce viability. Quinacrine, the most potent QBA, not only blocked autophagy, but at 20 μM it completely disrupted U251 cellular functioning, which was evidenced by a high level of PARP cleavage, as well as the absence of CHOP/GADD-153 and LC3B expression. These data showed that QBAs represent a novel class of compounds with the ability to inhibit autophagy and induce apoptosis in tumor cells.

Accumulation of QNX in Acidic Vacuoles and Cell Death

Quinacrine is the most potent QBA that we tested. It caused autophagosome accumulation, CHOP/GADD-153 induction, and PARP cleavage in a manner similar to CQ. However, it is unclear whether QNX initiates this activity in the same way as CQ. Since QNX fluoresces, it is possible to determine whether it accumulates within the acidic vacuoles, for example, lysosomes and late endosomes. To accomplish this, U251 cells were treated with QNX (10 μM) for 8 hours.
μM) in the presence or absence of bafilomycin A1 (200 nm), a vacuolar-type proton pump inhibitor that increases the pH of acidic vacuoles (Fig. 5A). U251 cells treated with QNX alone resulted in an increase in intracellular punctate fluorescence. In contrast, cells treated with bafilomycin A1 exhibited no such intracellular pattern. The amount of fluorescence was quantified using flow cytometry; the results showed QNX increasing fluorescence and bafilomycin A1 decreasing the signal (Fig. 5B).

**In Vivo Antitumor Activity Exhibited by QBAs**

Since we demonstrated that the most potent QBA, QNX, accumulated in acidic vacuoles, we set out to determine whether this effect could be replicated in vivo. In a subcutaneous human xenograft U87 glioma model, we treated nude mice with 50 mg/kg of QNX and harvested tumors after 24 hours. Tumor cells from frozen tissue samples from mice treated with QNX exhibited fluorescence, as compared with tumor specimens from untreated animals (Fig. 6 upper). In tissues from treated animals, the QNX formed a perinuclear punctate pattern of fluorescence, similar to the pattern observed when cells were treated with QNX in vitro. This pattern suggests that QNX selectively accumulates in tumor cell vacuoles in vivo.

To determine whether QNX can elicit the ER stress response in vivo, nude mice harboring subcutaneous U87 glioma tumors were treated with 25 mg/kg of MFQ, QNX, or QN. After 48 hours, tumors were harvested and analyzed for the ER stress marker CHOP/GADD-153 and apoptosis (Fig. 6 lower). In addition, CHOP/GADD-153 was induced in QNX-, QN-, MFQ-, and CQ-treated tumors, as compared with control tumors. The TUNEL assay for apoptosis demonstrated a significant increase in the number of...
Quinoline analogs inhibit autophagy

TUNEL-positive cells in QNX- and QN- > MFQ- > CQ-treated tumors, as compared with untreated controls. These data indicate that QBAs have the ability to induce ER stress potentially leading to apoptosis in vitro and in vivo.

Discussion

The tested QBAs displayed unique cytotoxic effects in drug-resistant tumor cells. For example, all tested QBAs killed glioma cells that were highly resistant and sensitive to TMZ. These results are consistent with evidence that overexpression of multidrug-resistant pumps contributes to CQ and QN drug resistance in *P. falciparum* parasites. The antitumor activity of the most potent compound, QNX, correlated with accumulation in lysosomes and resultant cytotoxicity. Bafilomycin A1, a vacuolar-type ATPase proton pump inhibitor, prevented the lysosomal accumulation of QNX, thereby reducing its cytotoxic effects.

We found that all tested QBAs displayed antitumor activity similar to that shown by CQ in several tumor types. Quinacrine was the most potent compound, followed by MFQ > HCQ > CQ > QN in vitro. However, all of the tested compounds could block autophagy, as indicated by an increase in the conversion of LC3B-I to LC3B-II (a marker for autophagosome accumulation) and an increase in the levels of polyubiquitinated proteins. In addition, an increase in CHOP/GADD-153 (an ER stress proapoptotic protein) and PARP cleavage (indicator of apoptosis) revealed that apoptosis was the cause of cell death.

Autophagy is the segregation of damaged or unwanted ER and cytoplasmic constituents into autophagosomes destined for lysosomal degradation. This process is not only essential for eliminating intracellular pathogens via the activation of the innate and adaptive immune responses, but is also noted for its role in maintaining ER and metabolic homeostasis in tumor cells undergoing chronic hypoxia and nutrient depletion. Next to the proteasome, autophagy is the primary pathway for the catabolism of cellular components for amino acid and energy recycling. However, too much autophagy may result in cell death if the degradation of cytoplasmic content proceeds to completion. Thus, the physiological relevance of autophagy in tumor cell survival and progression remains controversial.

Although others have shown that CQ exerts its effect through proteasome inhibition, we provide evidence to the contrary (Fig. 3C). In this study, we showed that QBAs represent a novel class of compounds that can exert their cytotoxic effects in tumor cells through their accumulation in lysosomes, by blocking autophagosome degradation, and by causing the accumulation of cytosolic-derived protein aggregates destined for lysosomal degradation; these processes initiate ER stress–induced apoptosis. This effect is reminiscent of their ability to accumulate in the AFVs of *P. falciparum* parasites and prevent heme detoxification as a means of inciting parasite death. Thus, not only are the QBAs a novel class of autophagy inhibitors, but they also represent a class of compounds that provides a rational ap-

![Image](image-url)
proach to antitumoral chemotherapeutic regimens from a parasite-host viewpoint.

Like most parasite-host relationships, *Plasmodium falciparum* and tumor cells are both capable of surviving under harsh conditions within their hosts. Intraerythrocytic *P. falciparum* ingests, catabolizes, and detoxifies erythrocyte-derived hemoglobin as a means of metabolically sustaining itself. Similarly, tumor cells catabolize unwanted or unnecessary ER and cytoplasmic protein aggregates via the autophagy pathway as a means of detoxifying and metabolically sustaining itself.

Quinoline-based antimalarial compounds incite parasite death by mitigating the catabolic and detoxification systems associated with *P. falciparum* and tumor cells by accumulating in AFVs and lysosomes, respectively. Baflo-

mycin A reduces the pH gradient between the cytoplasm and the lysosomes of tumor cells, thereby preventing the accumulation of the QBA QNX and attenuating its cytotoxic effects. We are currently investigating the potential adverse interactions between QBAs and proton pump inhibitors, such as omeprazole and pantoprazole, which are often prophylactically administered to prevent the onset of gastric ulcers in patients with brain tumors who are receiving dexamethasone. Whether these medications inhibit the overall efficacy of QBAs needs further assessment.

As regards malignant glioma, QBAs represent a viable therapy for newly diagnosed cases. Our demonstration that these compounds induce cytotoxicity in MGMT-negative cell lines, which subsequently become TMZ resistant, indicates that they might be used in patients in whom TMZ subsequently fails after initial responsiveness. Temozolomide induces autophagy in glioma cells as a protective mechanism; thus, inhibition of autophagy by QBAs would stimulate apoptosis. The QBA compound HCQ is currently used in clinical trials with TMZ (ClinicalTrials.gov Identifier: NCT00486603). However, our data suggest that either QNX or MFQ may be clinically superior to HCQ since both display the ability to penetrate the blood-brain barrier and possess greater cytotoxic effects than HCQ. Our data demonstrating QBAs’ effectiveness in treating TMZ-resistant glioma cell lines are especially promising. Chloroquine was found to increase progression-free survival but not overall survival; all trials were performed with CQ as a single agent. The combination of quinolones with cytotoxic drugs, such as TMZ, has not been widely used. A possible advantage of the QBA therapy is that the systemic side effects of QBAs are fairly minor. We selected cell lines that were initially MGMT negative as they represented lines that would have the best response to the standard current of care. However, when the cell lines became TMZ resistant, we demonstrated that QBAs maintain activity. These data suggest that patients whose disease progresses on standard TMZ chemotherapy may use QBAs either in combination with TMZ or as stand-alone therapy. Moreover, QBAs’ effectiveness in treating glioma cells regardless of their p53 status suggests its effectiveness in primary and secondary glioblastomas.

Finally, multilevel manipulation of ER stress and autophagy with combination treatments may severely enhance ER stress and greatly increase tumor cell death. Others have shown that MFQ inhibits sarcoplasmic/ER calcium ATPase (SERCA), thereby causing calcium release from the ER, an increase in misfolded proteins, and induction of the ER stress response. Thus, MFQ’s multilevel effect of increasing the burden of unfolded ER proteins targeted for lysosomal degradation while blocking autophagy and aggravating ER stress may contribute to greater potency, in comparison with the other QBAs. We previously demonstrated that combinations of chemotherapeutic compounds that manipulate the ER stress response at multiple levels hold clinical promise by synergistically inciting cell death. Now that we have established a novel class of autophagy inhibitors, it will be a matter of further characterizing the unique secondary qualities of each compound as a strategy for optimizing the activation of ER stress in combination with other clinically useful chemotherapies, such as proteasome and SERCA inhibitors, as a means of reducing the tumor burden while minimizing systemic side effects.

**Conclusions**

In summary, the antimalarial compounds investigated in this study hold promise as a novel class of autophagy inhibitors for the treatment of newly diagnosed TMZ-sensitive and recurrent TMZ-resistant gliomas.
