Children with spastic diplegia from cerebral palsy (CP) experience measurable improvement in their spasticity and motor function following selective dorsal rhizotomy (SDR). The role of this operation in the treatment of other spasticity causes is less well defined. A literature review was undertaken to survey outcomes from SDRs performed outside the CP population. Multiple sclerosis was the most common diagnosis found, accounting for 74 of 145 patients described. Selective dorsal rhizotomies have also been reported in patients with traumatic brain and spinal cord injuries, ischemic and hemorrhagic stroke, neurodegenerative disease, hypoxic encephalopathy, and other causes of spasticity. Outcomes from surgery are generally described as favorable, although postoperative assessments and follow-up times are not standardized across reports. Long-term outcomes are sparsely reported. Larger numbers of patients and more detailed outcomes data have the potential to form a basis for expanding the inclusion criteria for SDR.

Methods

A PubMed query was performed for English-language articles published between January 1980 and June
A case series of 30 patients undergoing SDR between 1989 and 1991 included only 20 patients with a diagnosis of CP.29 Causes of spasticity in the other 10 patients were cerebral in 7 and spinal in 3. These 10 patients included 2 patients each with hydrocephalus, near drowning, and hypoxia during heart surgery; 1 patient each with head injury, transverse myelitis, MS in the spinal cord, and myelomeningocele. Among the 27 total patients with spasticity of cerebral origin, 19 had spastic quadriplegia preoperatively and 8 had spastic diplegia. Surgical results were not individually specified by origin, although most patients were described as achieving significant benefit.

Results were described as satisfactory in 100% of cases. Patients with spastic quadriplegia consistently showed significant improvement in activities of daily living, as well as some inconsistent improvement in swallowing, reduced irritability, and seizure control. Among the 8 patients with spastic diplegia, the 2 patients who were ambulatory both improved their gait pattern, 4 nonambulatory patients improved their sitting and standing skills, and 2 previously nonambulatory patients attained assisted gait within 1–2 years after surgery. The patient with myelomeningocele also improved from nonambulatory to assisted gait.

A larger and more recently published report described outcomes in 154 patients undergoing SDR for various spasticity causes at a single institution over the years 1969–1998.28 The indication for surgery was described as spasticity that interfered with daily living and was resistant to conservative therapy. The most common diagnosis in this cohort was CP, which accounted for 60 patients. There were 52 patients with MS, 30 with spine trauma, 5 with head trauma, 4 with spinocerebellar degenerative disease, and 3 with amyotrophic lateral sclerosis (ALS). No other reports of SDR for ALS-associated spasticity were identified.

In this study, spasticity outcomes were measured with the Modified Ashworth Scale and assessed preoperatively, early (less than 1 year after surgery), and late (more than 1 year postoperatively). Patients with MS had a mean improvement on the Modified Ashworth Scale of 3 points early and 2 points late when compared with preoperative baseline. A similar pattern was observed for other causes: spine injury improved 3 points early, 2 points late; head injury 2 points early, 1 point late; and ALS 2 points early, 1 point late. The 4 patients with spinocerebellar degenerative disease maintained a 2-point improvement on the Modified Ashworth Scale from early to late follow-up.

Selective dorsal rhizotomy for non–cerebral palsy spasticity

Long-term efficacy was best in the CP patients, who were the youngest on average at surgery (12 years, compared with 42 years for MS, 28 years for trauma, and 51 years for ALS/spino cerebellar degeneration) and maintained a 3-point improvement on the Modified Ashworth Scale on late follow-up.

Other outcome measures were assessed as well, although not segregated by origin of spasticity. Lower limb spasticity, range of motion in affected joints, gait, bladder function, upper limb spasticity, and speech and cognition were all evaluated at early and late follow-up. All measures showed improvement, which did not appear to dissipate over time. All of the patients (100%) showed improved lower limb spasticity at early and late follow-up. There were no cases of worsening of any outcome variable in any patient at late follow-up, and 20% of patients who were nonambulatory preoperatively were able to walk at early and late follow-up.

The only other series with a comparable number of diverse patients described spasticity from MS in 6 patients, and 1 patient each with spinal cord injury, nonspecific myelopathy, and cerebral hemorrhage. Functional motility, pinprick sensation, and bladder function were all assessed preoperatively and 6–26 months postoperatively. Among the 6 patients with MS, all were paraplegic and wheelchair-bound preoperatively. Two patients became ambulatory postoperatively with assistive devices. One patient experienced 4 months of relief from deafferentation pain postoperatively, and another experienced lasting relief from spasticity-associated leg pain. There was 1 instance of transient deterioration in bladder function; otherwise, no adverse effects were reported. Spasticity was described as abolished in 4 patients, markedly reduced in 1 patient, and slightly reduced in 1 patient.

The patient with a spinal injury in this study underwent unilateral SDR for leg paresis and spasticity with deafferentation pain. At 20 months postoperatively, spasticity was abolished, ambulation had improved significantly, and pain was transiently relieved for 3 months. There was no change in normal bladder function. The patient with a diagnosis of nonspecific myelopathy was described as showing improvement in ambulation, and marked reduction in unilateral lower-extremity spasticity and associated pain at 12 months postoperatively. Normal bladder function and pinprick sensation were unchanged. The patient with cerebral hemorrhage was the only one to undergo cervical SDR, which was reported to markedly reduce spasticity in the affected arm with some return of functional motility. There was a possible slight deterioration in pinprick sensation.

A single-institution study that reviewed results of SDR on pediatric patients with spastic hemiparesis included 13 patients who underwent surgery between 2006 and 2008, 9 of whom had a diagnosis of CP. Of the remaining patients, 2 had a history of traumatic brain injury, 1 had a history of brain tumor, and 1 had an intracerebral hemorrhage from an arteriovenous malformation. All patients were reported to have demonstrated a decrease in resting muscle tone following SDR. Detailed outcome results were specified for the brain tumor patient, in whom stride length on the hemiparetic side improved from 25.5 inches preoperatively to 40 inches postoperatively, and time to walk 30 feet improved from 12.62 to 5.43 seconds. Overall results in this study were characterized as consistent with previously published results of SDR for spastic diplegia in randomized controlled trials.

Spasticity From Spinal Cord Injury

In addition to the previously described reports including brain and spinal cord injured patients, an early report from 1976 described the results of SDR in 4 patients with posttraumatic paraplegia as well as 5 patients with CP. Another patient with postmeningitis progressive spastic paraplegia was categorized with the trauma patients. The patients with CP underwent surgery at between 8 and 10 years of age; the 5 trauma patients underwent surgery between 17 and 23 years of age. Given the difference in ages and patterns of spasticity described in the 2 groups, direct comparison of outcomes is problematic. Outcomes in this trauma group appear similar to those from the posttraumatic patients in the previously described studies.

The postmeningitis patient in the present report had severely debilitating flexion spasm in the hips; postoperatively, the patient experienced significantly improved sitting ability. Of the remaining patients, 3 were ambulatory with assistive devices preoperatively, and all experienced significantly improved gait postoperatively with 2 able to walk without help. The last patient had a complete mid-thoracic spinal cord level and severe lower-extremity flexion spasm interfering with sitting. Selective dorsal rhizotomy permitted ventral posture, abduction, and sitting posture in this patient. The authors clarified that attempts were made to purposefully preserve some degree of useful spasticity, particularly in quadiceps femoris and gluteus muscles, to assist with walking and upright posture.

An additional case report was published in 2002 describing a 26-year-old man with a diagnosis of systemic lupus erythematosus who subsequently developed transverse myelitis. The patient experienced significant progressive spastic paraplegia, dysthetic pain, and impaired bladder control, rendering him bedridden and dependent in activities of daily living. The patient underwent SDR 1 year after onset of transverse myelitis. He was described as completely independent in ambulation and self-care at 10 months postoperatively, without adverse effects from the surgery.

Spasticity From Stroke

A report of 2 patients who developed severe unilateral lower-extremity spasticity following ischemic stroke described good results from unilateral SDR. Both patients had very poor tolerance of oral muscle relaxants. The first patient was 68 years old at the time of an acute, distal, left anterior cerebral artery infarct that resulted in progressive, severe, and painful right leg spasticity over the next 6 months. The patient could stand with a cane but not walk. A unilateral right-sided SDR restored the patient’s ability to walk with a cane and significantly improved activities of daily living for more than 1 year after surgery.

The patient in the second report suffered a right-sided putaminal stroke at 89 years of age that resulted in severe
left hemiparesis and spasticity, causing intolerable pain in the leg that was particularly acute when the patient was moved by others (during transfers). Unilateral left SDR resulted in complete relief of spasticity-associated pain, with muscle tone in the leg evaluated as normal to hypotonic.

**Spasticity From Neurodegenerative Disease**

In addition to the previously described 3 patients with ALS and 4 with spinocerebellar degeneration, there has also been another report of SDR used in 2 cases of spasticity secondary to neurodegenerative disease. At 18 years old, the first patient was given a diagnosis of hypomyelination with atrophy of the basal ganglia and cerebellum, having developed severe progressive spastic quadriplegia and dysarthria between ages 2 and 12 years. At age 19 years, the patient underwent placement of an intrathecal baclofen pump, which was removed 2 weeks later due to infection, although caregiver satisfaction with this treatment modality was described as minimal. Selective dorsal rhizotomy was subsequently performed, which resulted in the disappearance of leg spasticity. The postoperative course was complicated by a urinary tract infection, recurrent migrating arthritis, and ventral dislocation of the L-1 spinous process requiring surgical revision. Over the next 3 years, the clinical course remained progressive, although spasticity never returned in the legs.

A second patient with an uncharacterized mitochondrial genetic disorder and progressive spastic quadriplegia underwent SDR at age 8 years of age with disappearance of leg spasticity. Over the following 3 years, the legs remained stable with oral baclofen treatment, but the disease process progressed; spasticity in the arms increased, leading to disabling contractures. Extension posturing of the trunk (arching of the back from severe muscle spasm) eventually interfered with sitting.

**Spasticity From Congenital Brain Malformation**

A relatively recent study described SDR in the setting of disorders of neuronal migration. The report included only 2 patients, but both had spastic diplegia secondary to congenital brain malformations. These patients represented 1.77% of the 113 SDR cases performed over 15 years at 1 institution, and were the only patients without a diagnosis of CP. The first patient had a diagnosis of hemimegalencephaly and underwent surgery at 3.5 years of age. Preoperatively, this patient was ambulatory. Over the reported 5-year follow-up period, significant improvements were sustained in ambulation and lower-extremity range of motion.

The second patient had open-lip schizencephaly and left frontal cortical dysplasia that led to a spastic triplegia involving the left arm and both legs. Surgery was performed at age 6 years. In this patient, who was also ambulatory preoperatively, significant improvement in gait and lower-extremity muscle tone was observed 2 years postoperatively.

**Spasticity From MS**

Previously described studies included a total of 59 patients with spasticity from MS, among patients with other diagnoses. An additional study focused specifically on the results of SDR in patients with spasticity from this cause. This series was composed of 15 patients with a diagnosis of MS who underwent SDR between 1974 and 1981. Thirteen of the patients were women, the duration between diagnosis of MS and surgery ranged from 6 to 30 years (average 12 years), and age at surgery ranged from 31 to 58 years old. Postoperative follow-up in this cohort ranged from 1 to 8 years.

Preoperative functional status in the patients was described as completely bedridden in 11 patients and wheelchair dependent in the other 4 patients. Postoperatively, 8 patients were able to walk with crutches, 1 was able to stand upright, 3 were wheelchair dependent, and only 2 remained bedridden. Twelve of the patients demonstrated significant improvement in spontaneous flexion postures. However, 6 patients did undergo further orthopedic surgeries for contractions within 2 months of their SDR. Two patients exhibited deterioration of motor function, described as corresponding to 1 spinal level. It was also noted that SDR partially reduced sensation in 1 or more spinal levels in 13 patients, although this was described as having no practical consequences. The conclusion from this report was that 12 of 15 patients experienced satisfactory symptomatic improvement following SDR.

**Spasticity From Hereditary Spastic Paraparesis**

Hereditary spastic paraparesis refers to a family of genetically and clinically diverse disorders that have progressive lower-extremity spasticity and weakness in common. These disorders are generally characterized by mode of inheritance and symptoms. At least 52 different mutations have been associated with this disease process, which can be transmitted in an autosomal dominant, autosomal recessive, or X-linked fashion. Hereditary spastic paraparesis is characterized as uncomplicated if the spasticity is associated only with mild lower-extremity loss of proprioception and sphincter dysfunction, or complex if it associated with any other neurological problems.

Only 1 report was identified that included a patient with hereditary spastic paraparesis who underwent SDR. This study examined whether adherence to strict patient selection criteria for SDR resulted in improved outcomes, although their criteria explicitly included hereditary spastic paraparesis as an appropriate indication for surgery. Of 53 children referred to the authors for possible SDR, only 19 were determined to be suitable surgical candidates. The SDR cohort included 1 of 4 patients initially evaluated who had a diagnosis of hereditary spastic paraparesis; specific rationales for excluding the other 3 patients were not given. Detailed clinical evaluations were performed both preoperatively and an average of 18 months postoperatively. Although individual patient data were not reported, collective results showed statistically significant improvement in a large number of measurements. Walking speed, step length, hip and knee extensor power, ankle dorsiflexion range and power, and ankle plantar flexion range were among the parameters that improved. Patients with hereditary spastic paraparesis may benefit from further detailed analysis of potential benefits from SDR.
Selective dorsal rhizotomy for non–cerebral palsy spasticity

Discussion

This study was motivated in part by a 2-year-old patient referred to our neurosurgery program for possible unilateral SDR for fixed, distal, left lower limb spasticity. The patient had extensive polymicrogyria of the right perisylvian region and no other historical, clinical, or radiographic findings suggestive of CP. This patient was ambulatory with an orthosis, with no other assistive device necessary. As of the most recent evaluation, the family did not wish to pursue neurosurgical intervention.

A meta-analysis of SDR trials that randomized CP patients with spastic diplegia to surgery in addition to physical therapy, or physical therapy alone, concluded that the surgical arm exhibited superior results after 1 year in a statistically significant fashion. Outcome measures that showed improvement included the Ashworth scale for spasticity and the Gross Motor Function Measure for motor function. A direct relationship between percentage of dorsal root fascicles transected and functional improvement was observed. Subsequent large nonrandomized studies have found similar functional improvements that persist at up to 26 years postoperatively.

The presumed mechanism by which SDR alleviates spasticity is by modulation of afferent inputs to lower motor neurons to compensate for a loss of upper motor neuron regulation, although the details of this mechanism are poorly understood. The most common imaging finding associated with CP is periventricular leukomalacia, which is associated with nerosis of the periventricular and subcortical white matter. This region is the most vulnerable to hypoperfusion during hypotension, and may suffer reperfusion injury from oxygen free radicals and excitatory amino acids. It has been speculated that periventricular leukomalacia–associated injury to the projection fibers from the primary motor cortex is the underlying basis for spastic CP. The topographic arrangement of these projection fibers would lead leg fibers, traversing closer to the ventricle, to be injured preferentially over arm fibers, depending on the extent of the periventricular leukomalacia.

Muscle tone is determined largely by alpha motor neuron output in the ventral horn of the spinal cord; excitatory and inhibitory modulation may be disrupted by periventricular leukomalacia–injured descending motor fibers. Spasticity is generally characterized as the result of abnormal feedback loops between dorsal and ventral neurons. Ventral rhizotomy does not yield acceptable results. This model implies that success of SDR should be independent of specific features of the upper motor neuron disease process, as is reflected to some degree in its broad efficacy across the heterogeneous CP population. The data reviewed in this report suggest that SDR may be appropriate for an even wider range of upper motor neuron disease processes and may even extend to upper motor neuron pathologies that are extracranial, progressive, or both.

Our literature review identified many reports of patients undergoing SDR for diagnoses other than CP, although only 4 pathologies were represented in more than 2 cases: MS, spinal cord injury, neurodegenerative disease, and traumatic brain injury. The 74 patients with MS comprised the largest cohort by diagnosis, across 1 study specific to this disease process and 3 studies that included multiple diagnoses. Only 1 of the latter studies specified diagnosis-specific outcomes; the 52 patients with MS in that study showed a mean improvement of 2 points on the Ashworth scale at more than 1 year after surgery. The MS–specific series, although describing 12 of 15 outcomes as satisfactory, did not use Ashworth scoring as part of the patient evaluation. Similar heterogeneity in patient evaluation and outcome reporting was found in the spinal cord injury, traumatic brain injury, and neurodegenerative disease cohorts. Although the MS data are promising, there is insufficient evidence to consider any of these diagnoses to be indications for SDR.

Limitations to the available data are clear. While certainly justifying further investigation, there is an inadequate empirical basis for widespread expansion of SDR outside of established diagnostic criteria. Studies have suggested that SDR may be inappropriate in some patients, such as those more than 10 years of age, and some authors continue to question its efficacy even within the most thoroughly studied populations. It is also the case that the full complexity of spinal motor circuits is not completely understood, nor is the role and mechanism of upper motor neuron and sensory input into these circuits. It is therefore our conclusion that SDR, as an irreversible neuroablative procedure, should continue to be performed only with great caution.

Conclusions

Selective dorsal rhizotomy is a well-studied and effective therapy for lower-extremity spasticity resulting from CP and may be beneficial in other types of upper motor neuron disease. This procedure has not been systematically studied in contexts outside of CP. Multiple sclerosis and traumatic spinal cord injury are the most commonly reported non-CP diagnoses in patients who have undergone SDR. Patients with traumatic brain injury, near drowning, progressive neurological disease, spastic hemiplegia, and age greater than 45 years have undergone SDR despite falling outside common inclusion criteria for surgery. Although reported results are described as satisfactory, no standardized outcomes data are available outside of the CP population. Limited information from case reports is suggestive that patients with a variety of diagnoses may derive some benefit from this procedure at least in the short to intermediate term. Consideration should be given to prospective multiinstitutional enrollment of patients in a standardized outcomes database.
