OBJECT Microvascular decompression is a safe and effective procedure to treat hemifacial spasm, but the operation poses some risk to the patient's hearing. While severe sensorineural hearing loss across all frequencies occurs at a low rate in experienced hands, a recent study suggests that as many as one-half of patients who undergo this procedure may experience ipsilateral high-frequency hearing loss (HFHL), and as many as one-quarter may experience contralateral HFHL. While it has been suggested that drill-related noise may account for this finding, this study was designed to examine the effect of a number of techniques designed to protect the vestibulocochlear nerve from operative manipulation on the incidence of HFHL.

METHODS Pure-tone audiometry was performed both preoperatively and postoperatively on 67 patients who underwent microvascular decompression for hemifacial spasm during the study period. A change of greater than 10 dB at either 4 kHz or 8 kHz was considered to be HFHL. Additionally, the authors analyzed intraoperative brainstem auditory evoked potentials from this patient cohort.

RESULTS The incidence of ipsilateral HFHL in this cohort was 7.4%, while the incidence of contralateral HFHL was 4.5%. One patient (1.5%; also included in the HFHL group) experienced an ipsilateral nonserviceable hearing loss.

CONCLUSIONS The reduced incidence of HFHL in this study suggests that technical modifications including performing the procedure without the use of fixed retraction may greatly reduce, but not eliminate, the occurrence of HFHL following microvascular decompression for hemifacial spasm.

Patient Selection

With approval of the institutional review board, we retrospectively reviewed the medical records of all patients undergoing MVD for HFS, performed by the senior author (R.S.), at the University of Pittsburgh Medical Center between January 2012 and October 2013. All patients presenting with clinical features of HFS underwent preoperative electromyography testing for detection of an abnormal motor response or “lateral spread” elicited via stimulation of the zygomatic branch of the facial nerve and recorded from the mentalis muscle, confirming the diagnosis. At this time, patients also underwent preoperative brainstem auditory evoked potential (BAEP) testing. All patients underwent thin-slice T2-weighted MRI to evaluate vascular compression along the centrally myelinated portion of the facial nerve. Additionally, both preoperative and postoperative bilateral pure-tone audiometry was obtained for all patients. All medically stable patients, including patients of advanced age, those who had undergone prior MVD, or those with a history of facial botulinum toxin injections, were included in the study based on a positive abnormal motor response of the facial nerve and radiographically apparent neurovascular compression.

Operative Technique

In all patients, MVD of the facial nerve was performed using techniques described in previous studies as well as recent modifications designed to minimize fixed cerebellar retraction, which are detailed below. A self-retaining retractor was never used during any portion of the procedure. Strict management of fluids was initiated in preoperative holding, with the administration of intravenous mannitol (0.25 g/kg), based on experience, was given less than 500 ml). A modification of the physiological dose of mannitol (0.25 g/kg), based on experience, was given 30 minutes prior to the start of the procedure, as well as an 8-mg dose of dexamethasone. Initial intraoperative BAEPs were recorded prior to patient positioning. Patients were turned in the lateral decubitus position. Operative modifications included the use of a small retromastoid craniectomy measuring approximately 1.5 cm × 2 cm, created with an electric drill (Midas; Stryker). In addition, the neurosurgeon and neurophysiologist used agreed-upon “warning criteria” of the BAEPs to manage the flow and alter the mechanics of the operation, as described in detail in the section below. After exposing the facial nerve from the pontomedullary sulcus to its root detachment point, MVD was performed along the centrally myelinated portion of the facial nerve, with microscopic or endoscopic visualization in all patients. Finally, following a watertight closure, cement cranioplasty was performed.

Brainstem Auditory Evoked Potentials

Real-time continuous BAEPs were recorded from all patients undergoing MVD for HFS. The ear ipsilateral to the MVD was stimulated using alternating rarefaction and condensation clicks with at least an 85-dB sound pressure level (SPL) intensity. The contralateral ear was stimulated with a white noise of 65-dB SPL and responses recorded at baseline and at various times during the procedure. Clicks were delivered at a 17.5-Hz frequency, with an observation interval of 12 msec, and each average was calculated from the results of 512 trials. Recording electrodes were positioned as follows: Channel 1, vertex to left ear mastoid; Channel 2, vertex to right mastoid; and Channel 3, vertex to C-2. The amplifier band pass was 100–1000 Hz for all channels. Baseline responses were obtained after anesthesia induction and patient positioning.

Alarm Criteria

To prevent inadvertent auditory nerve injury during retractorless surgery, we modified the traditionally accepted alarm criteria for BAEP changes. Traditionally, persistent decreases in amplitude greater than 50% of Wave V and persistent absolute latency increase of the peak of Wave V, which equals or exceeds 0.5 msec, were considered significant. We modified the criteria so there was constant and frequent communication with the surgical team regarding the changes. The surgeon was specifically informed when the latency changes exceeded more than 0.25 msec and if there was any change in amplitude. “Persistent changes” represent differences in amplitude or latency for 2 or more consecutive trials to reduce the effect of technical issues such as noise.

Analysis of Neurophysiological Parameters

We analyzed the amplitude and latency of Wave V and the interpeak latencies of Waves I–V, as described in a previous study. Analysis was performed at various stages during the surgery: 1) baseline, after intubation and positioning of the patient; 2) dura open, the epoch when the opening of the dura mater was documented; 3) change max, the maximum change in latency or amplitude recorded compared with average baseline waveform, including epochs when the responses were completely lost; and 4) on skin, the last epoch recorded.

Audiometry

Pure-tone audiometry was performed as described by Ying et al. Preoperative audiometry was performed between 1 and 142 days (mean 2.1 days, median 1 day). Postoperative audiometry was performed between 1 and 16 days (mean 2.1 days, median 1 day). HHHL was defined as an increase of at least 15 dB in the hearing threshold at either 4000 Hz or 8000 Hz. Nonserviceable hearing loss was defined by change in pure-tone audiometry of greater than 50 dB and speech discrimination scores of less than 50%, by the American Academy of Otolaryngology-Head and Neck Surgery classification system.

Statistical Analysis

Data were presented as mean ± standard deviation as well as median for continuous variables and proportion for categorical variables. The differences between ipsilateral and contralateral audiogram thresholds were assessed by Wilcoxon signed-rank tests because of the skewness of the data. The analyses were carried out by SAS version 9.3 (SAS Institute Inc.).
In the present study, the incidence of HFHL was 7.4% and 4.5% ipsilateral and contralateral to the side of surgery, respectively. We were unable to detect a significant difference in the incidence of HFHL between the 2 sides (p = 0.72). Additionally, no difference in HFHL was noted following first-time or repeated MVD. A prior study, conducted by the same neurophysiological monitoring team but a different neurosurgeon, at our institution included postoperative audiometry in every patient to detect HFHL.28 In this study, the incidence of HFHL following MVD for HFS was found to be 50% and 25% on the ipsilateral and contralateral sides, respectively.28 The authors hypothesized that drill-induced noise and transient loss of CSF during surgery may impair hearing in the high-frequency ranges on both the ipsilateral and contralateral sides. Since both the previous and present studies used identical criteria in defining HFHL, the lower prevalence of HFHL in the current study may be due to a practice paradigm shift instituted at our institution by a new director of the Center for Cranial Nerve Disorders (R.S.), designed to minimize iatrogenic damage from the manipulation of neural tissue during the surgical procedure. This includes avoidance of fixed brain retraction, consistent use of alarm criteria of the BAEPs, and the optimization of neuroanaesthesia delivery.

**Retractorless Surgery**

In recent years, some neurosurgeons have attempted to reduce the use of fixed retraction in supratentorial and infratentorial operations. The main goals of this trend have been to reduce the incidence of iatrogenic microtrauma and ischemia within the brain parenchyma. Techniques such as optimal patient positioning for gravity retraction, dynamic retraction, and flexible microsurgical instrumentation have all been used to reduce or eliminate the use of standard retractors.3,26 During MVD for HFS, fixed cerebellar retraction has historically been used to expose the cranial nerves.15,17,25 When performing the operations in the 2008 study, the previous cranial nerve neurosurgical team at our institution routinely used both fixed and dynamic cerebellar retraction.28 While this offers the advantage of providing excellent exposure of the facial nerve, fixed retraction comes at several costs. Albin et al. have shown that excessive brain retraction may adversely affect cerebral perfusion pressure and somatosensory evoked potentials with resultant brain injury.1,2,16 Additionally, this type of manipulation may also lead to operative manipulation (e.g., stretching) of the vestibulocochlear nerve, leading to iatrogenic injury and subsequent hearing loss and balance issues.16 Accumulating experience and evidence...

Results

Preoperative and postoperative audiograms were available for 67 of 85 patients who underwent MVD during the study period. Of these 67 patients, 5 patients (7.4%) had HFHL on the ipsilateral side and 3 patients (4.5%) had HFHL on the contralateral side. Two patients (3.0%) had bilateral HFHL following the operation and were included in both the ipsilateral and contralateral groups (Tables 1 and 2).

The mean pure-tone thresholds at each frequency are compared before and after the operation for both the ipsilateral and contralateral side in Table 3 and Fig. 1. Eleven (16.4%) of 67 patients had undergone a previous ipsilateral MVD for HFS, while the remainder were undergoing their first operative procedure for this condition. Mean pure-tone thresholds for both the ipsilateral and contralateral sides are presented for patients undergoing first-time MVD in Table 4 and repeated MVD in Table 5.

No patient experienced a contralateral nonserviceable hearing loss and 1 patient (1.5%) experienced an ipsilateral nonserviceable hearing loss. Since this patient had hearing loss across all frequencies including 4 kHz and 8 kHz, she was also counted among those with ipsilateral HFHL. None of the 11 patients in this series who had previously undergone an ipsilateral MVD for HFS experienced HFHL or nonserviceable hearing loss.

No significant change in the amplitude or latency of Wave V of BAEPs was noted in patients with and without HFHL. Similarly, the interpeak latencies of Waves I–V following the operation were noted in patients with and without HFHL. No significant difference in the incidence of HFHL was noted following first-time or repeated MVD. A prior study, conducted by the same neurophysiological monitoring team but a different neurosurgeon, at our institution included postoperative audiometry in every patient to detect HFHL.28 In this study, the incidence of HFHL following MVD for HFS was found to be 50% and 25% on the ipsilateral and contralateral sides, respectively.28 The authors hypothesized that drill-induced noise and transient loss of CSF during surgery may impair hearing in the high-frequency ranges on both the ipsilateral and contralateral sides. Since both the previous and present studies used identical criteria in defining HFHL, the lower prevalence of HFHL in the current study may be due to a practice paradigm shift instituted at our institution by a new director of the Center for Cranial Nerve Disorders (R.S.), designed to minimize iatrogenic damage from the manipulation of neural tissue during the surgical procedure. This includes avoidance of fixed brain retraction, consistent use of alarm criteria of the BAEPs, and the optimization of neuroanaesthesia delivery.
suggest that if the ultimate goal of an operation (e.g., clipping of an aneurysm, resection of a vascular malformation or tumor) can be achieved without a retractor, a retractor should not be used in brain surgery.

**Intraoperative Neuromonitoring and Alarm Criteria**

Evidence suggests that the use of BAEP monitoring during MVD reduces the incidence of hearing loss, though a minority of surgeons disagree. In our series, we did not find any significant difference in latency and amplitude of Wave V of BAEPs during MVD in patients with and without HFHL. As part of the institutional paradigm shift, we used alarm criteria developed by the senior author (R.S.) and based on both experience and modifications to the guidelines set forth by Polo et al. When the latency of Peak V increased by greater than 0.5 msec from baseline, all instruments were removed from the wound and the operation was stopped until the latency returned to baseline. It is not uncommon for several, short surgical pauses (i.e., lasting minutes) to take place during these procedures. These pauses are important regardless of whether fixed retraction is used, because the shaft of a surgical instrument can dynamically retract and lead to changes in evoked potentials, as the focus of the surgical team is on the tip of the instruments and the deep vascular and neural anatomy. If the surgical instruments are not removed and the surgery continues, even in the face of no fixed retraction and a mild to modest delay in signals, an increase in morbidity may occur. This is in contrast to the previous surgical team at our institution, which continued to operate if there was a latency of Peak V greater than 0.5 msec and only removed surgical instruments and ceased the operation when there was a diminution in the amplitude of Peak V. We feel that the important aspect of implementing successful alarm criteria is in the communication between the surgical and neurophysiological teams. This communication needs to be open and dynamic, and occur in real time. Any hesitation in reporting of changes can lead to delay in surgical intervention and iatrogenic injury. This aspect of intraoperative monitoring in MVD procedures cannot be stressed enough.

**Optimal Neuroanesthesia Care**

Optimal neuroanesthesia delivery is an important com-

component of any neurosurgical procedure. During MVD, optimal care begins with management of intravenous fluids. In our practice, the administration of intravenous fluids is limited to an arbitrary target of less than 500 ml prior to opening of the dura, in an effort to avoid iatrogenic intracranial hypertension. A modified physiological dose of mannitol is administered 30–60 minutes prior to skin incision. With this low dose, recognizable disturbances in electrolyte concentrations, renal function, and coagulation have not been noted. Hemodynamic stability is maintained with a combination of inhalation and intravenous anesthesia. Optimal patient positioning facilitates gravity-enhanced relaxation of the cerebellum and appropriate venous return. Blood loss is kept to a minimum (i.e., usually less than 25 ml per procedure). No patient in this series required a blood transfusion.

Drill-Induced SNHL

While it is clear that operative manipulation of the vestibulocochlear nerve can result in SNHL, drill-generated noise created during craniotomy has also been suggested as a cause for HFHL.4,28 Drill-generated noise may damage hearing by either mechanical stretch of the inner-ear structures or through metabolic changes in the cochlear cells.6 Farzanegan et al. showed that patients undergoing supratentorial craniotomy for brain tumor resection developed SNHL that was restricted to the higher frequencies.3 Despite taking precautions to reduce operative trauma to the vestibulocochlear nerve, using a retractorless technique, a small number of patients in this study did have HFHL following MVD. While some of the HFHL observed may be due to operative manipulation that can never be truly avoided, drill-induced acoustic damage remains a possible etiology in these patients.

Study Limitations

In addition to the small sample size, a limitation of this study is that although every patient who underwent MVD

for HFS during the study period was asked to undergo both a preoperative and postoperative audiogram, data from both hearing tests were only available for 67 of 85 consecutive patients (78.8%), which compares favorably to the previous report from our center in which both preoperative and postoperative hearing data were available for 94 of 152 (61.8%) of patients.28 This could actually lead to overreporting of HFHL prevalence if patients who did not feel that they experienced a postoperative change in hearing status did not have sufficient motivation to obtain a postoperative hearing test. Additionally, a difference in the median time to postoperative audiometric follow-up limits the ability to compare incidences of HFHL between the present study (median time to audiogram 2 days) and the previous study (median time to audiogram 7 days).28 Finally, this study is limited by the lack of available long-term audiometric data on the patients with HFHL. Whether this type of hearing deficit changes over time is not known. To answer this question, we have begun to collect long-term audiometric data on all patients with HFHL.

Conclusions

SNHL after MVD is an often underdiagnosed condition. The magnitude of the problem is unknown due to ambiguous or differing measures among studies of what constitutes SNHL. This debilitating complication is often mitigated by the use of BAEPs. Performing the procedure without the use of fixed retraction may help reduce both HFHL and SNHL. Drill-related noise and/or CSF diversion, however, may still contribute to postoperative HFHL and SNHL, as evidenced by contralateral hearing loss that was observed in this and our previous study. Long-term studies and longitudinal audiogram information from other patients will contribute to a greater understanding of this problem.
